Scientific Officer (male, with an honours degree), for genetical and cytological research—The Secretary, Plant Breeding Institute, Trumpington, Cambridge (January 30).

Assistant Lecturer in Biochemistry—The Registrar, The University, Sheffield (January 31).

Boots Medical Research Fellow (medically qualified), to undertake research in one of the following fields: Pharmacology, Therapeutics, Pathology, Bacteriology, Medicine, Surgery, or Obstetrics and Gynæcology—The Registrar, The University, Sheffield (January 31).

Lecturer in Bacteriology—The Registrar, The University, Sheffield (January 31).

Assistant Lecturer in Biochemistry—The Registrar, The University, Sheffield (January 31).

Assistant Lecturer in Mathematics—The Registrar, University College of North Staffordshire, Keele, Staffordshire (February 1).

Lecturer/Senior Lecturer in Mechanical Engineering at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, February 2).

Senior Lecturer or Lecturer, and a Lecturer in the Department of Mechanical Engineering, University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, February 8)

Chair of Dermatology at the Institute of Dermatology—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 10).

Reader in Laryngology at the Institute of Laryngology and Otology—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 11).

Experimental Officer/Assistant Experimental Officer (electronic engineer with experience of pulse techniques) at the National Physical Laboratory (Metallurgy Division), Teddington, Middlesex, for the upkeep and development of the following equipment: nucleonic counters, X-ray detectors, spectrographic source units, automatic timers, voltage regulators, mass spectrometers, and wide band amplifiers—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting Ref. D.633/9A (February 12).

LECTURER IN PHYSICS, and a LABORATORY SUPERINTENDENT IN THE DEPARTMENT OF PHYSICS, Fourah Bay College, Sierra Leone (University of Durham)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 12).

ASSISTANT LECTURER or LECTURER (with a degree in pure science) IN AGRICULTURAL ZOOLOGY at Canterbury Agricultural College, University of New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C 1 (New Zealand and London, February 15).

CHAIR OF ORGANIC CHEMISTRY at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W C 1 (February 15).

SENIOR LECTURER and a LECTURER IN PHYSICS at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, February 29).

SENIOR LECTURER IN AGRICULTURAL ECONOMICS at Canterbury Agricultural College, University of New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W C.1 (New Zealand and London, February 29).

SENIOR LECTURER or LECTURER IN EDUCATION at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1, or from the Registrar of the University (New Zealand and London, February 29).

ASSISTANT TUTOR or TUTOR IN PHARMACEUTICS; an ASSISTANT TUTOR or TUTOR IN PHARMACEUTICAL CHEMISTRY; an ASSISTANT TUTOR or TUTOR IN PHARMACOGNOSY; and an ASSISTANT TUTOR IN PHARMACOLOGY at the New Zealand School of Pharmacy—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (March 1).

BIOCHEMIST or MICROBIOLOGIST (with an honours degree), to work in the field of bacterial metabolism—The Secretary, Medical Research Council of Ireland, 50 Merrion Square, Dublin (March 1).

PETER NICOL RUSSELL CHAIR OF MECHANICAL ENGINEERING at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, March 15).

ASSISTANT PHYSICIST (with an honours degree in physics and postgraduate experience in radiation or nuclear physics) IN THE DEPARTMENT OF PHYSICS APPLIED TO MEDICINE, for duties concerned mainly with assisting in the organization of practical work, demonstrations and teaching aids for postgraduate courses for the M.Sc. degree in Radiation Physics, and other postgraduate courses in radiological physics and protection—The Secretary, Department of Physics Applied to Medicine, Middlesex Hospital Medical School, London, W.1.

ASSOCIATE PROFESSOR or ASSISTANT PROFESSOR (theoretical physicist, preferably with experience and main interest in the field of nuclear theory), to teach courses at the senior and postgraduate levels and to carry on research—The Head, Department of Mathematical Physics, University of Manitoba, Winnipeg, Canada.

BIOLOGIST (with a good degree in physiology or zoology and considerable research experience, preferably with spermatozoa); and a BIOCHEMIST (with a good degree in biochemistry or chemistry, and research experience with polysaccharides or proteins, preferably involving work with animals), to join a small research team investigating cervical mucus, with particular reference to problems of fertility —The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 59/17.

BIOLOGIST (with a strong leaning towards botany, and capable of teaching biology to *A* level and botany to *S* level); and a CHEMIST (capable of teaching the subject to *A* level)—The Head Master, Westminster School, Dean's Yard, London, S.W.1.

CHIEF TECHNICIAN (trained in hæmatology, able to supervise staff and plan systematic experimental work)—The Personnel Manager, Jewish General Hospital, 3755 Cote Street, Catherine Road, Montreal, Quebec, Canada.

GRADUATE ASSISTANTS (qualified to pursue M.Sc. and Ph.D. work) IN CHEMISTRY—The Chairman, Department of Chemistry, McMaster University, Hamilton, Ontario, Canada.

INDEXER (female, preferably graduate)—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, near Maidenhead, Berks

INSTRUCTOR or ASSISTANT PROFESSOR; POSTDOCTORATE FELLOWS; and SCHOLARS IN THE DEPARTMENT OF PHYSICS—The Head, Department of Physics, University of British Columbia, Vancouver, B.C., Canada.

ISOTOPE TECHNICIAN (preferably with a knowledge of biochemistry or electronics), for a specialized laboratory dealing with the diagnosis, treatment and research in thyroid disorders—Hospital Secretary, New End Hospital, Hampstead, London, N.W.3.

LABORATORY TECHNICIAN (A.I M.L T. or B.Sc.), for routine hospital biochemistry—The Secretary, Group 9 Pathological Laboratory, 6 Rickmansworth Road, Watford.

LECTURER (with an honours degree in mathematics or statistics, with teaching and research or industrial experience involving the application of mathematics to scientific and engineering problems) IN MATHEMATICS—The Registrar, College of Technology, Ashley Down, Bristol 7.

PROFESSOR'S SECRETARY (preferably graduate, especially botany or horticulture), to work at the University of Reading Horticultural Research Laboratories—The Assistant Bursar, The University, Reading.

RESEARCH ASSISTANT (with some previous laboratory or animal experience), for work on the biochemistry of the eye—The Secretary, University College Hospital Medical School, University Street, London, W.C.1.

RESEARCH FELLOW IN THE DEPARTMENT OF MEDICAL PHYSICS, for work concerned with the physical problems arising from the use of ionizing radiations in medicine—The Secretary, Royal Free Hospital School of Medicine (University of London), 8 Hunter Street, London, W.C.1.

SCIENTIFIC OFFICER (with a first- or second-class honours degree in physics or equivalent) at the National Physical Laboratory (Standards Division), Teddington, Middlesex, to apply modern techniques, for example, optical interference, to precision measurement in first place of quantities, such as length and pressure, and later of fundamental physical quantities and constants—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.577/9A.

SENIOR PHARMACIST at the London Chest Hospital—The House Governor, London Chest Hospital, London, E.2.

TECHNICAL ASSISTANT (preferably with G.C.E. "A" level, or better, in physics, chemistry and biology), for research in cell structure and nucleic acids, using the electron microscope, etc.—The Director, M.R C. Biophysics Research Unit, King's College, Strand, London, W.C.2.

CONTROL OF RADIOACTIVE WASTES

THE recent Monaco Conference on Radioactive Waste Disposal (see *Nature* of January 2, p. 1) was held at about the same time as a Bill dealing with the subject was introduced in the House of Lords. At the present time, disposal of radioactive waste in Great Britain, by organizations other than the United Kingdom Atomic Energy Authority, is governed by the same regulations as apply to ordinary domestic and industrial wastes. With the growing use of radioactive substances by a diversity of bodies and because of certain hazards peculiar to the disposal of radioactive wastes, it was realized that these regulations were probably inadequate. In 1956, at the invitation of the Minister of Housing and Local Government, an expert panel was appointed by the Radioactive Substances Committee with the following terms of reference :

"To ascertain the nature and quantity of radioactive waste likely to arise in the foreseeable future ; to advise on the best methods of securing that the waste is disposed of safely ; and to advise whether any new legal provisions or amendments to existing legislation are necessary to ensure safe disposal, and, if so, to advise on the form which the new provisions or amendments should take."

The report of this Committee is contained in a recent White Paper* and the recommendations of the Committee are effectively incorporated in the Radioactive Substances Bill, introduced in the House of Lords on November 13. The Bill provides that the temporary powers by which the discharge of radioactive wastes by the Atomic Energy Authority and other licensed nuclear installations are exercised by the Minister of Housing and Local Government and the Minister of Agriculture, Fisheries and Food, and in Scotland the Secretary of State, will be made permanent. Other users of radioactive materials will be obliged to register their premises with the appropriate Minister (in England and Wales, the Minister of Housing and Local Government and in Scotland, the Minister of State). No disposal of radioactive waste will be permitted except on authorization from the appropriate Minister or Ministers. The Ministry of Housing and Local Government and the Secretary of State for Scotland will, in addition, have power to arrange a national disposal service to handle wastes that cannot safely be dealt with in the area in which they originate. The cost of this service will be chargeable to users of the service.

Both the principles and recommendations emerging from the report of the Committee should be studied by all present and future users of radioactive substances. The views expressed may be briefly summarized. There must be adequate justification for the use of any source of ionizing radiation, no matter how small. Subject to such justification and with suitable precautions, the use of radionuclides should be encouraged. It is not possible to dispose of radioactive wastes without adding to the background irradiation to which the public is exposed, but it is possible to keep this increase well within acceptable limits. Irrespective of cost, it must be ensured that the discharge of radioactive waste does not endanger the health of any individual member of the public, and further, in the terms of the White Paper, "in considering whether a given discharge should or should not be permitted, it is necessary to decide whether the radiation from the discharge, when added to that from all other sources of radiation, is likely to result in a genetic hazard to the nation as a whole ; from this point of view it is as much the concern of, for example, London as of Manchester if the inhabitants of either are exposed to ionizing radiations". It is obvious that local control of discharges would not enable such decisions to be taken, and that a national body staffed by suitable experts would be necessary. When considering the level of permissible discharge, irradiation of the public by other sources, notably normal background, X-ray and fall-out, has to be considered. The Committee suggests that the gonad irradiation arising directly from waste disposal, to which the whole population is exposed, should in no circumstances be permitted to exceed an average dose of 1 r. per person per 30 years, and also emphasizes that it would expect that, with reasonable precautions, the average dose would be maintained much below this level. The recommendation of the Committee for the setting-up of a National Disposal Service in no way suggests that local disposal is unsatisfactory ; on the contrary, local disposal, wherever feasible, is recommended. It is anticipated that the primary function of the National Disposal Service will be to dispose of highly active wastes of long half-life.

A detailed and quantitative picture of the present scale and range of radioactive waste disposal emerges from the report of the Committee. It would appear that, with a few notable exceptions, particularly in the luminizing industry, the hitherto limited controls have so far ensured that radioactive wastes have been disposed of in an acceptable manner. The Committee has been in much greater difficulty, however, when attempting to forecast the quantity of radioactivity to be disposed of in the future. Thus, when considering wastes likely to arise from private reactors, its comment that "we find it difficult to estimate the magnitude of the wastes likely to be produced in these enterprises", emphasizes the need for an organization responsible for radioactive waste disposal on a national basis and for the frequent review of limits and methods of disposal.

---

* The Control of Radioactive Wastes. Pp. 46. (Cmnd. 884.) (London : H.M. Stationery Office, 1959.) 2*s*. 6*d*. net.

The Committee was in obvious difficulty in suggesting a limit for the irradiation dosage that could be received by the population as a result of waste disposal, in that "there is no agreed permissible genetic dose and there is no agreed allocation of dose to the different ways in which the population is irradiated". Whatever the research effort, it is difficult to imagine a quick answer to this problem. For immediate use, it would appear reasonable to suggest limits, as the Committee has done, which are considerably less than those which informed medical opinion regards as maximal. The report also indicates the need for considerable research in a number of other fields where information is lacking. Thus, when speaking of the discharge of liquid wastes to rivers, the Committee comments that "we know all too little of the absorption on river muds, the absorption into weeds and the take-up by cress". A research inquiry would appear to be required to establish the fate of radionuclides disposed of in sewage systems. It should not be impossible to ascertain what proportion of radionuclides, particularly those such as radiostrontium which are taken up by plants, pass through sewage disposal works and what proportion is retained in the sewage sludge, which may be used as a fertilizer. The report warns of the need for further research before highly active fission products produced as waste from the processing of fuel elements be dumped into the sea. The repeated reference to the lack of experts with the knowledge to deal with the problems of waste disposal poses the question as to whether adequate steps have been taken to ensure the training of sufficient personnel for the efficient working of the proposed central authority.

GEOPHYSICS FOR THE ENGINEER

Geophysical Surveys in Mining, Hydrological and Engineering Projects, 1958

Pp. viii+270. (The Hague, 30 Carel V. Bylandtlaan: European Association of Exploration Geophysicists, 1959.) 16.50 florins; 4.50 dollars.

THOSE who have followed the growth of geophysics since the early 'twenties will remark the happy circumstance that has allowed the publication of this excellent volume of case-histories to occur during Prof. J. M. Bruckshaw's term as president of the European Association of Exploration Geophysicists. Prof. Bruckshaw was a member of the original team which, under Broughton-Edge, produced one of the classics of applied geophysics, based on tests of all the different physical tools against a series of geological structures in Australia.

When it became apparent that geophysical methods could locate potential oil reservoirs, the oil industry application swamped all others. There has been a tendency, as with oil-well drilling, for the tools to be elaborated instrumentally, but, as Prof. Bruckshaw pointed out in his presidential address to the European Association of Exploration Geophysicists, there have been no fundamental changes in the methods that were developed thirty years ago. It is possible that present geophysical methods in the oil industry have already been pushed beyond their economic limits, and it may be opportune to take another look at how the mining and civil engineers use geophysics.

The engineer, whether looking for ore-bodies, locating water-supplies or studying the foundations of buildings or dam sites, cannot afford the luxury of rapid coverage of large areas with routine magnetic, gravity and seismic measurements. He must find the most suitable tool or combination of tools—including the drill—to solve his geological problem. In one respect, of course, the technical problems of the engineer are simplified, since all his underground structures are much shallower than most oil reservoirs, and often cheap and rapid electrical prospecting methods are adequate. However, the case-histories do show a proper appreciation of how geophysical tools should be used in geological work, as, for example, in some of the Rhône valley investigations, where electrical surveys were supplemented by seismic refraction measurements.

It is instructive to the oil geophysicist to read of the wide variety of successful applications of geophysical methods. In Yugoslavia, for example, ancient Roman mining activity is being extended by the exploration of a whole zone of electrical anomalies. In Finland, swamp-covered ore deposits are revealed by magnetic and electromagnetic surveys. The search for uranium-vanadium ores in Colorado in 1940 led to the use of the Geiger counter as a new prospecting tool It is pleasant also for those who have spent a great deal of time listening patiently to the claims of water diviners to see that great success has been achieved in the State of Illinois by using resistivity surveys to locate comparatively small pockets of water-bearing sand and gravel. The drill has shown that in hundreds of surveys the interpretations are 90 per cent correct, a better result than can be obtained by divining.

This collection of past experience should prove of great benefit to civil engineers, since there are many cases, such as the proposed Channel Tunnel or the new Forth Bridge, where the application of geophysical methods can supplement and extrapolate the information obtained traditionally by boring.

T. F. GASKELL

ELEMENTARY PARTICLES

The Theory of Elementary Particles

By Dr. J. Hamilton. (International Series of Monographs on Physics.) Pp. xii+482. (Oxford: Clarendon Press; London: Oxford University Press, 1959.) 75*s*. net.

IT must be said immediately that this is not a narrative book that aims to introduce one to elementary particles or indeed to interest one in them by persuasion at all. It is a book for the professional which deals with the mathematical formalism and techniques that have been found useful for our description of elementary particles and their interactions. The particles themselves, of course, figure and are the subject of a table at its end. They are used, however, rather more to illustrate the formalism than as the subjects of the work itself. The formalism presented is 'useful' in the sense that it is of immediate application in our everyday handling of the elementary particles. There is very little attempt to discuss mathematics in a quasi-philosophical framework as a source of concepts. In other words, this is a book that tells you how to do the standard calculations about elementary particles using the techniques that have been evolved since the War. It is therefore an extremely useful book and will be of the greatest practical value, particularly as a very thorough and general introduction for theoretical students. It is a book for which a great need has been felt for many years, and it satisfies that need. The writing is of considerable clarity, and it will not be merely the theoretical student who profits by the use of this work. The experimentalist who does not mind a little hard work is well able from this text to put himself in contact with the 'right' way of thinking about particles and their interactions. Helpful examples abound and the author has to be thanked for the large number of 'hints' that he gives in liberal footnotes to sustain the weaker brethren. In short, it is a technical work that will satisfy the professional theoretician without repelling the curious experimentalist. The author is to be both congratulated and thanked.

The early chapters describe the setting up of classical fields and lay stress on general invariance properties of a relativistic origin. Then follow discussions of the quantization of boson and fermion fields and the interaction of fields. This first half of the book is essentially introductory in character and sets out the formalism at some length in a clear and agreeable way. Renormalization methods are then introduced with a discussion of the S-matrix and scattering theory, followed by Heisenberg and interaction representation operators. The Chew-Low theory is discussed in some detail, and there is a good treatment of dispersion relations. Throughout the book the author rightly stresses the relation between the invariance properties and selection rules, and these are discussed at some length. There are final chapters on polarization analysis and the foundations of field quantization.

This is basically a book to be learnt from and to be used rather than one purporting to summarize the state of play. It will be widely appreciated.

D. H. WILKINSON

PETROLEUM INDUSTRY

Advances in Petroleum Chemistry and Refining

Vol. 1. Pp. xv+641. Vol. 2. Pp. xviii+634. Edited by Kenneth A. Kobe and John J. McKetta, Jr. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 109*s*. per volume.

THE petroleum industry has always maintained large and active research and development organizations, the contribution of which to the advancement of science is published in patent or technical literature in ever-increasing quantity. The annual reviews of "Petroleum Technology", published by the Institute of Petroleum, permitted a rapid appraisal of the state of knowledge in any particular aspect of the industry, but the increasing quantity of technical publications which had to be reviewed caused the editors to cease this most useful publication in 1952. No adequate replacement has yet appeared. Certain specific aspects of the subject have been collected in such works as the "Physical Chemistry of Hydrocarbons", edited by A. Farkas (1950), and the "Chemistry of Petroleum Hydrocarbons", edited by B. T. Brooks, C. E. Boord, S. S. Kurtz and L. Schmerling (1954). These contain chapters by a number of authors dealing with the state of knowledge of a particular aspect of the chemistry of hydrocarbons, but there is apparently no intention of publishing additional volumes which might serve to bring the subject-matter up to date.

A real need exists for this purpose, which has been recognized by the editors of the new publication, "Advances in Petroleum Chemistry and Refining". The editors state that the various aspects of the petroleum industry, economics and future trends, unit operations and design, refinery processes, petrochemicals and mechanical equipment, will be dealt with by specialist authors in separate chapters of a series of volumes which "over the course of several years will assume the character of a reference book". The two volumes under review constitute the first of this series, and contain a number of chapters devoted to each of the five group headings outlined previously. The individual authors are all active in research or development within the petroleum industry and many are already recognized as outstanding authorities on their subject.

The task of the individual authors has been simplified in that they are not bound by any restriction concerning the years to which their review must be devoted, nor apparently is it considered necessary to include a complete bibliography on the subject at the end of each chapter. Each author makes a critical appraisal of the state of knowledge in his particular subject at the time of writing and illustrates his comments by reference to such published work as he considers necessary for his purpose. In some instances, such as the excellent chapters on "Solvent Refining" (A. W. Francis and W. H. King) and on "Solid Polymers from Surface Catalysts" (H. N. Friedlander and W. Resnick), a fairly complete bibliography has been given, but in general the editors have not duplicated the bibliographies published annually in the Unit Process and Unit Operations review of *Industrial and Engineering Chemistry*. This permits a certain leisurely approach to the subject; the authors do not feel they have to cram a number of original references into every sentence but can deal at some length with the fewer references they choose to examine. The result is what our American friends might describe as an 'all time high' in technical review literature. The chapters are readable, and although not all of the same high standard are nevertheless interesting and in many cases stimulating.

Chemists and technologists in the petroleum industry will appreciate the critical treatment of the technical and patent literature by several of the authors, while the non-specialist will find much of general interest, particularly in the section dealing with economics and future trends. It is not often that books of this nature, intended for a specialized section of industry, can be recommended for general student reading, but in this case the books can be recommended to degree students and research workers in chemistry or chemical engineering. In particular, the chapter on "Solid Polymers from Surface Catalysts", by H. N. Friedlander and W. Resnick, is an excellent account of a rapidly developing field of chemistry which as yet has not been described in current text-books. Those interested in industrial developments will find the chapter dealing with "Raw Materials for the Petrochemical Industry", by P. W. Cornell and V. N. Hurd, of particular interest.

If the high standard of the first two volumes is maintained in future publications the series will prove a most welcome addition to the libraries of petroleum technologists, but it will only be welcome on these already overburdened shelves if it maintains its selective character and does not become a reference book.

F. MORTON

CHEMICAL AND BIOLOGICAL ACTION OF RADIATIONS

Radiolyse de Liquides Organiques

Par Milton Burton. Polymérisations Amorcées par les Radiations Ionisantes. Par A. Chapiro et M. Magat. Effets des Rayonnements de Grande Énergie sur les Polymères. Par A. Charlesby. (Actions Chimiques et Biologiques des Radiations, Troisième Série. Collection dirigée par M. Haissinsky.) Pp. iv+222. (Paris: Masson et Cie., 1958.) Broché, 4,000 francs; cartonné toile, 4,800 francs.

Les Peroxydes Organiques en Radiobiologie

(Organic Peroxides in Radiobiology). Par R. Latarjet *et al.* (Actions Chimiques et Biologiques des Radiations, Quatrième Série. Collection dirigée par M. Haissinsky.) Pp. viii+156. (Paris: Masson et Cie., 1958.) Broché, 2,800 francs; cartonné toile, 3,600 francs.

IN the third volume of Haissinsky's series of monographs the dominant theme, in each of the three topics discussed, is a physicochemical interpretation of the principal radiation effects. The various authors give at the outset a compact account of the theoretical principles which are used in the interpretation, and, in consequence, the articles serve as useful introductions to complex and expanding subjects. A further advantage of the approach is to focus attention on the studies which have led to results of a definitive character. It becomes apparent from the discussions that a great deal of published work in this field is of limited value, due to the fact that inadequate attention has been given to experimental conditions, such as purity of materials, methods of irradiation, and so on.

The theoretical background presented in the article by Burton is to some extent covered by Gray in the first volume of this series, but the reiteration, with greater emphasis on the role of excitation processes, and attention throughout to photochemical analogy, seems appropriate to the purpose in hand. His account of the radiolytic effects includes a range of organic liquids in various chemical classes, although the results obtained with hydrocarbons, which are the most susceptible to interpretation, occupy the major part of the discussion. The other two articles are authoritative and notably lucid. They will no doubt be read by radiobiologists in search of clues, but they also merit the attention of industrial polymer chemists.

The fourth volume is devoted to the proceedings of a colloquium concerned with an evaluation of the concept of organic peroxides as causal agents in radiobiological damage. Sixteen papers are presented, commencing with a useful account of recent work on the nature of the peroxides resulting from the autoxidation of fats. (The absence of literature references to this paper is an unfortunate omission.) The other topics range from the radiochemical production of peroxides in *in vitro* systems (cumene, polystyrene, nucleic acids), to the biological effects of peroxides and the influence of oxygen on radiation effect produced in a number of biological systems. Th discussions on the individual papers, and a valuabl discussion on the main theme of the colloquium, ar freely recorded in this volume.

The high standards set in the first two volume of this series are well maintained in the presen additions..

W. ANDERSON

SCIENTIFIC MEDICINE FOR POSTGRADUATES

Lectures on the Scientific Basis of Medicine

Vol. 7, 1957–58. (British Postgraduate Medica Federation: University of London.) Pp. xii+496+ 33 plates. (London: The Athlone Press, Universit of London, 1959.) Distributed by Constable and Co. Ltd. 45*s*. net.

UNTIL a relatively short time ago, experienc was the great postgraduate teacher, but th progress of knowledge in the past thirty years ha made it clear that experience alone is no longe enough. Other teachers are necessary, capable o helping medical men and women to implement th new ideas and discoveries in their daily work whatever that may be. Twenty-three of these teacher have prepared their lectures for this book. It is th seventh in a well-known series, and the subject covered are as wide as before. They range fron studies of the growth of viruses to biochemica deficiencies in the whole animal, and include lecture on hæmatology, biochemical genetics, cell regeneration, pharmacology, minutiæ of the eye and ear, th stability of collagen and ageing processes in th female reproductive tract.

The subjects could only have been presented b an equal number of specialists, and they display th complexity of the biological framework as it i gradually becoming revealed to us. No one man ca comprehend more than a fraction of it all in detail but these lectures year by year are mostly simpl enough to allow the interested reader to draw hi own conclusions as to the bearing, if any, they ma have on his daily round. Nevertheless, the spoke word is often easier to follow than the written one and some of these lectures must be studied with car to get the most out of them, and for many peopl time and interest will be the limiting factors.

This series of books is described as a venture i postgraduate education, intended for graduates i medicine looking forward to careers as teachers an consultants in medicine and surgery and their specia branches, as well as for those seeking careers i research and teaching in the medical sciences. This i a very fair appraisal and the sponsors may congratulate themselves on their venture. It is only on of the many now being made in postgraduat education. The short courses lasting from one t three days now being held at the Royal College o Physicians, at Cambridge and in many other parts o Britain, have rather a different appeal, but judgin by their success, whether the proceedings are published afterwards or not, there is evidently a widespread demand for knowledge among specialists an practitioners, and an appreciation of the efforts whic are being made to provide it for them.

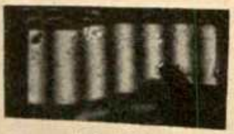
R. A. MCCANCE

INTERFEROMETRIC STUDIES ON SYNTHETIC DIAMONDS

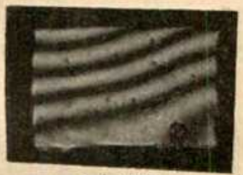
By Prof. S. TOLANSKY, F.R.S., and Dr. I. SUNAGAWA
Royal Holloway College, Egham, Surrey

In a recent article we reported on some findings on synthetic diamonds[1]. Using a very sensitive phase-contrast microscope we observed the following features which do not occur on natural diamonds, namely: (*a*) cubic faces of unusual smooth quality; (*b*) growth spirals on some such cubic faces; (*c*) dendritic diamonds; (*d*) very frequent linear slip lines, especially on octahedral faces (such slip is found in natural diamonds, but much less frequently).

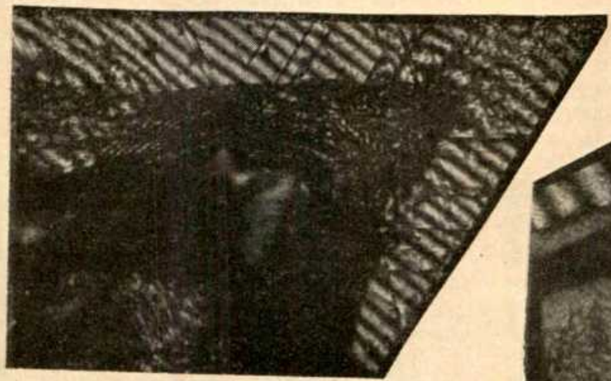
We have now succeeded in obtaining interferogram on quite a large number of synthetic diamond faces. Owing to the micro-character and irregularity of shape of the material at our disposal, we have so far only succeeded with two-beam interferometry, but we are still pursuing attempts to apply multiple-beam methods. We have available both the samples reported upon previously and also a new sample (kindly sent to us by Dr. Bundy of the General Electric



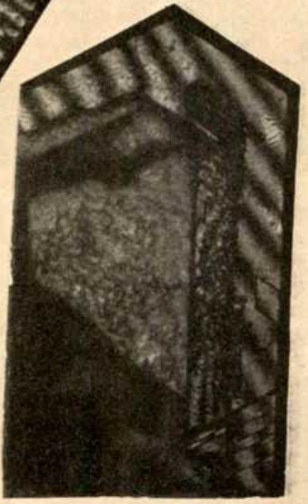
1. (×250)



2. (×250)



3. (×250)



4. (×250)

8. (×175)

Co., Schenectady). The older sample reveals many cubic as well as octahedral faces. The crystals in the second sample are perhaps twice as large linearly (some $\frac{1}{5}$ mm.) and are almost exclusively octahedra. Interferograms from the earlier sample will be considered first.

The interferograms were obtained by matching against glass. The fringe visibility found calls for comment. Normally the matching of gem-quality diamond against glass produces fringes of moderate visibility, because of the two very different reflecting coefficients. Here, on the contrary, many of the fringe patterns are of such excellent visibility that it must be concluded that the reflecting coefficients of the diamond surfaces are relatively low, indeed not very different from that of glass. This fringe visibility is particularly noticeable on some, but not all, of the fringe patterns, and it is quite possible that the few cases with poor visibility are due to a nearer approach in reflectivity to the typical natural value. We have no firm evidence as yet as to the possible causes for a reduction in reflectivity, that is, as to whether the defect lies in the crystal or is due to surface film. Figs. 1 and 2 show fringes on two fine smooth cubic faces. The smooth uniformity in the fringe patterns is ample confirmation of our earlier statement that synthetic cubic faces can at times show a remarkable degree of perfection. Fig. 1 shows an excellent plane (within the limitations of the two-beam fringes). The good fringe visibility is worthy of comment. Fig. 2 also shows a smooth, nearly flat, surface, but with a hillock over one corner, about one fringe in height. It is more than likely that this is an unresolved growth spiral, since we have most frequently seen such spirals starting out from corners. Two-beam interferometry cannot be expected to resolve the spirals we have previously described.

We consider next, in Fig. 3, an octahedral face, and this interferogram reveals three commonly found characteristics: (*a*) First is the marked skeletal or hopper character of the face. It reveals a level, fairly plane, parapet or rim and within this is a hollow region. (*b*) Second, the fringes on the rim or parapet show that this region is smooth and of good quality. (*c*) Third, and particularly noticeable, are the crystallographically oriented slip lines, some of which end in the surface.

We have found numerous frequently interesting variations of the hopper or skeletal formation and they are particularly well brought out by the fringe system, in that the upper rim is that which contacts the optical flat. Fig. 4 is one further example from many. There are local variations in fringe visibility here and it is well to remember that the good visibility comes probably from the defective regions, the bad visibility on the contrary being attributable to a more normal reflectivity. Indeed, there is a suspicion on the originals that the regions of good visibility of fringes are patchy and perhaps coated.

A few dendritic crystals have responded to interferometric analysis and part of one such dendrite is shown in Fig. 5. The fringes show that both the 'backbone' and the 'ribs' are flat and smooth, and indeed co-planar, more or less.

We come now to the consideration of the interferograms given by the second batch of crystals, largely octahedra. Here again the hopper character is common, as before, and the slip lines are frequent. Fig. 6, taken with blue light, reveals the hopper character and shows strongly marked slip running right across the crystal, even across the central hollow. It seems fairly certain that the slip here has taken place very late in the history of the crystal. By the employment of different wave-lengths the heights of the steps have been determined. They vary from 500 to 15,000 A.; a good deal more than might have been expected.

Fig. 7 shows a characteristic of the slip lines which we find to be very common, namely the way in which they terminate. Many do so in the surface, and the fringe displacements on either side show quite clearly that the slip step is inclined to the plane of the surface of the crystal. It has, in fact, the character of a screw dislocation.

Finally, we direct attention to the occasional appearance of the familiar growth trigons seen so often on natural octahedral faces. Their visibility, when shallow, is much enhanced by interferometry, in accordance with familiar principles. Thus trigons are clearly seen in Fig. 7, and more so in Fig. 8. Fig. 8 is the same face as Fig. 7; but here we have arranged to have a very high interferometric dispersion by setting the face almost exactly parallel to the optical flat. The result is to create the usual enhanced interferometric contrast and this shows up the trigons well.

The occurrence of well-defined linear trigons on diamonds which have grown very rapidly and which show not the slightest sign of etch or solution effects is in complete harmony with our long-held views that trigons are essentially a growth phenomenon. As so often observed in natural diamonds, so too in synthetic diamonds the trigons frequently 'sit' on a linear dislocation (Fig. 9).

BIOLOGY OF THE SOUTHERN COLD TEMPERATE ZONE

IN opening a discussion meeting of the Royal Society, held during December 10–11, which was attended by some twenty invited contributors, including many from overseas, the leader, Prof. C. F. A. Pantin, stressed the importance of understanding natural distribution patterns of animals and plants. The chief problem of to-day is not how to maintain a maximal rate of technological advance, but to predict and control the biological future of the Earth. The study of the development and adaptations of faunas and floras in the past, and of their response to climatic and geological factors, may provide vital information for the future.

The Southern Cold Temperate Zone is the least known of the world's major climatic belts, and information concerning it is widely scattered. Because of the wide separation of its land masses there has been a tendency for the separate consideration of their floras and faunas. This discussion was the first attempt during this century at a general synthesis of the available biological information about the region as a whole.

The Royal Society's interest in the Southern Temperate Zone arose in connexion with the Darwin–Wallace Centenary, which it celebrated by sending a five-man expedition to southern Chile, in the southern summer of 1958–59. This party carried out geological and ecological surveys, and made observations on species with a disjunct distribution linking Chile and New Zealand (M. W. Holdgate*). Originally the Royal Society had been interested simply in this trans-Pacific relationship; however, as a result of the expedition, it was realized that this should be considered within the broader context of the whole southern circumpolar region.

The Southern Cold Temperate Zone includes a large proportion of ocean: the climate of its land masses is therefore unusually closely related to marine temperatures and currents (G. E. R. Deacon). Southwards the Antarctic Convergence provides a sharp and fairly constant boundary: the land within it, like Antarctica itself, South Georgia and Bouvet Island, is largely ice-capped. Northwards, the Sub-Tropical Convergence fluctuates more widely but includes nearly all the temperate southern islands. Southern South America, New Zealand and Tasmania are the only truly continental southern temperate areas.

According to C. J. F. Skottsberg, many plant families must be regarded as Palæo–Antarctic, and are still largely confined to the southern cold temperate region (for example, Eucryphiaceae, Gunneraceae, Escaloniaceae, Proteaceae). Some members of these are strictly continental in distribution, but even those genera reaching oceanic islands fall roughly into either 'balanced', 'South American', 'Neozelandic–Australian' or 'Afro–Indian' groups. *Acaena*, widely spread around the zone, exemplifies the first type, *Pernettya* and *Fuchsia* the second, and *Hebe*, *Coprosma* and *Nothofagus* the third. Viewing the pattern as a whole, the paths of migration of these groups seem to radiate from the Antarctic. Their present distribution does not seem readily explicable in terms of trans-oceanic dispersal, and seems to accord best with an initial segregation in Antarctica itself and subsequent outward spread (C. J. F. Skottsberg and G. E. DuRietz). Such a hypothesis is strongly supported by geological evidence (R. A. Couper). In the late Cretaceous and early Tertiary *Nothofagus* species and Podocarpaceae were abundant in west Antarctica (Seymour Island), Australia, New Zealand, Kerguelen and southern South America. Many species disappeared from the southern areas in the late Pliocene, at which time a northward shift seems to have occurred. These plants have never been found as fossils in the northern hemisphere or the tropics, and their present extension into New Guinea and Indonesia is regarded as recent.

Vegetationally, southern Chile and New Zealand, as the two main southern temperate areas, have much in common (E. J. Godley). In both the wet, oceanic, western regions are dominated by evergreen rain forests in which *Nothofagus* species are prominent. The New Zealand forests are, however, much richer in species. Other differences include the lack of deciduous beeches in New Zealand (there are seven species in Chile), and the greater importance of podocarps as forest dominants there. Only the open 'Magellanic moorland' of south-western Chile is regarded as truly Sub-Antarctic. Bog vegetation of the 'carpet' type, formed by species of *Astelia*, *Donatia*, *Gaimardia*, *Oreobolus*, and similar plants, rather than *Sphagna*, prevails in this region and also in the New Zealand Sub-Antarctic islands, and is considered an important indicator of Sub-Antarctic conditions.

The southern islands also show fairly clear similarities in the structure of their vegetation. Only the northernmost (Tristan, Gough, Amsterdam, Juan Fernandez, Auckland, Campbell) have scrub, which is always of microphyllous prostrate evergreen trees bearing a heavy lichen and bryophyte epiphytic cover and with an under-storey rich in ferns (N. M. Wace). Large tussock-grasses (usually *Poa* spp.) form a characteristic formation on steep sub-maritime slopes throughout the zone. 'Wet heath' formations of Gramineae, Cyperaceae, ericoid shrubs and bryophytes form a higher belt, with areas of wind-eroded feldmark and montane grassland highest of all. These Sub-Antarctic lowland formations have a striking physiognomic resemblance to the vegetation of high tropical mountains (N. M. Wace and C. Troll); a fact which may be related to the small annual temperature variation in both regions (C. Troll).

In the Quaternary, southern Patagonia had at least three major glaciations. Pollen analysis reveals a post-glacial pattern of climatic and floristic change strikingly like that in the northern hemisphere (V. Auer). There is evidence that such processes are still going on, and the forest-steppe boundary in Tierra del Fuego seems to be fluctuating rapidly. Volcanic ash bands occur at constant horizons throughout most of Fuego-Patagonia, the three latest being dated at 9,000, 5,000 and 2,200 years before the present. These may perhaps be correlated with climatic changes (H. H. Lamb), and fluctuations in the position of the west wind belt and ocean currents are certainly to be expected to follow changes in temperature. A striking agreement in dating exists between the third Patagonian eruption and an ash band in the peats of Gough Island in the mid-Atlantic (U. Hafsten). However, pollen analyses of the Tristan–Gough group peats shows that the present mild oceanic climate, and the present vegetation, has persisted there for at least the past 5,000 years. The main vegetational changes seem to have followed human discovery (U. Hafsten).

The terrestrial fauna of the southern Chilean forests becomes progressively impoverished as one passes from the rich, warm-temperate, Valdivian type into the poorer Magellanic forests of the south, but the latter contain few species absent from the former (G. Kuschel). The western Magellanic moorlands are even poorer faunistically; on the other hand, the open, semi-arid steppes of eastern Patagonia are comparatively rich. Many southern Chilean invertebrate groups have a disjunct distribution in South America and Australasia, paralleling that of the plants, and some of the insects belong to orders which are strictly continental and known from no oceanic island (for example, Plecoptera, Megaloptera) (G. Kuschel and M. W. Holdgate). An outward migration from the Antarctic in the Mid-Tertiary may provide the best explanation of their present range. The terrestrial fauna of the southern oceanic islands, even of relatively warm examples like the Tristan–Gough group, is even more strikingly impoverished. Only 132 terrestrial invertebrates have so far been recorded from these islands. Many of these show a strong South American affinity, and the insects are believed to have been derived predominantly from that continent by airborne immigration in the prevailing westerly winds (M. W. Holdgate). Occasionally South American Lepidoptera and land birds appear as stragglers in the islands. The Tristan group also shows slight faunistic affinity with St. Paul and Amsterdam, but none with the colder and more southerly oceanic islands. These do, however, share something of a truly circumpolar fauna with relations to South America and New Zealand. Most of these islands are believed to be young, and their faunas likewise. In the Tristan–Gough group this hypothesis is supported by botanical evidence (N. M. Wace).

---

* The names appearing in brackets in the text of this article are those of the contributors to the meeting whose papers are here summarized. It is hoped to publish all the major Contributions in the *Proceedings of the Royal Society* (B).

Within the littoral marine fauna, it is possible to recognize a distinct southern circumpolar element paralleled in the algal flora (G. A. Knox). Many of the species are dominants and give a characteristic aspect to southern temperate shores. A schematic classification of these zonations can be derived, although distinct species groups are peculiar to each southern continent. Africa, despite an upwelling of cold Sub-Antarctic water off the south-west coast, has little truly southern cold-temperate faunistic relationship (T. A. Stephenson), a fact paralleled in its terrestrial invertebrate fauna (P. Brinck) and its flora (R. S. Adamson). In planktonic organisms, also, the southern waters have circumpolar, clearly zoned forms which show abrupt specific limitations near the convergences (N. A. Mackintosh). The Antarctic penguins also show somewhat of a circumpolar distribution with a radiation to distinct and geographically limited species farther north. In contrast, the shelf fauna of the Antarctic itself has a very high (70–80 per cent) incidence of endemism, and while many of its component species spread all around the continent they show no clear relationship with the animals of the other southern land masses (N. A. Mackintosh).

Oceanic birds are of profound ecological significance in the south, since they breed in vast numbers on many islands. One major vegetation type—tussock grassland—may be in part a biotically induced formation (N. M. Wace). Yet despite their abundance, these birds have so far been imperfectly studied and the validity of their taxonomic definition is still questionable in many cases (R. C. Murphy). Many species make great migrations, and may act as dispersal agents for seeds and invertebrates: this role may be filled especially by juvenile petrels, which often fly while still bearing down contaminated from the nest burrow (R. A. Falla).

There is no doubt that the Southern Cold Temperate Zone possesses many features as a whole. Despite wide separation, there are many floristic and faunistic similarities between southern America and New Zealand and Australasia, and this applies also to the structural features of almost all the southern cold–temperate vegetation types. There is geological evidence which accords with that of present distribution in suggesting a common origin for such groups in a temperate Antarctic during the Tertiary. In contrast, no terrestrial vertebrates have a distribution of the true southern cold–temperate type (P. J. Darlington), and indeed, except for birds, land vertebrates seem to be largely absent from the region. Those that do occur appear to be recent immigrants from the north. Ecological rather than distributional factors may underlie this anomaly. It is evident that many features of this zone reflect the exacting requirements of the high-oceanic climate. The species-poverty of the southern islands and of south-west Chile no doubt depends in part on dispersal difficulties and upon recent ice-retreat, but it may well also derive from the narrow and specialized range of habitat conditions. The Southern Cold Temperate Zone indeed emerges as an area with a highly characteristic biology, and with a climate more profoundly influenced by the temperature and circulation of the sea than any other major world zone (C. F. A. Pantin). It is apparent, however, that much more work remains to be done there. Native faunas and floras are fast vanishing before the onset of northern hemisphere species introduced by man; yet there is virtually no southern island or mainland area which can be said to have received adequate study in all respects.

M. W. Holdgate

AN INTERNATIONAL TAGGING TEST WITH SALMON (*SALMO SALAR* L.) SMOLTS

By A. SWAIN and P. E. CARADINE

Freshwater Fisheries Laboratory, Ministry of Agriculture, Fisheries and Food

FOR many years various experiments have been carried out in Great Britain and other European countries to investigate the migratory habits of the Atlantic salmon (*Salmo salar* L.). Much of the work has been undertaken to obtain further information about the movements of salmon in the sea, the proportion of smolts returning as adult fish and the percentage of spent fish surviving to spawn in following years, and in recent years thousands of salmon smolts have been tagged in Britain and Scandinavia.

Nearly all these experiments have involved the marking or tagging of the fish in some way. Numerous methods of tagging have been tried both with internal tags and external ones attached to various parts of the fish's body. The tagging of salmon smolts presents special difficulties because of the difference in the size of the fish between tagging and recapture. The lengths of most of the smolts tagged lie within the range 12–18 cm.; but when the fish are recaptured after spending one, two or more years at sea, the lengths will be between 50 and 100 cm.

or even longer. It follows that a tag which is attached to such a small fish must not restrict its freedom of movement unduly, but at the same time the tag must be such as to remain on the fish for a number of years. Also, in most instances, the tag must be clearly visible when the adult fish is caught. Although the type of tag has varied considerably, most of the workers have attached it near the base of the main dorsal fin of the fish.

In Great Britain, the number of tagged smolts being recaptured as adult fish has rarely exceeded 2 per cent. Norwegian returns have been somewhat lower, whereas in Sweden, the average figure has been between 5 and 10 per cent, with even higher figures for some of the larger smolts tagged. These high returns have been obtained both with Baltic salmon, where the fish are caught commercially on the feeding grounds, and with west-coast salmon, where they are caught along the coast near the mouths of the rivers.

The efficiency of different tagging methods was discussed at a symposium held by the Salmon and Trout Committee at the meeting of the Conseil International pour l'Exploration de la Mer, in October 1958. It was proposed that there should be an interchange of tagging methods. As a result, during April and May 1959, a number of Scottish smolts were tagged by Scottish, English and Swedish workers, using their own tags and techniques. Later on in May we visited Norway and Sweden in order to apply our English methods to the tagging of Scandinavian smolts.

All the smolts tagged in Norway and Sweden during this experiment were hatchery-reared and were two years old. We used two types of tag, one of which was a small silver plate, the other a small square of 'Ivorine' (celluloid)[1]. These tags were serially numbered, and for both types a short length of fine silver wire was used as a means of attachment. The Swedish tag (Carlin tag)[1] consisted of a small piece of cardboard coated with celluloid, with a message printed on one side of the cardboard. A serial number appeared on the other side. The tag is attached by means of a moveable hinge to a short length of soft stainless-steel wire which in turn is hinged to another stainless-steel wire, both ends of which are separately inserted into the body of the fish and twisted together on the other side. The tag used by the Norwegians is called the Lea hydrostatic tag[1] and is used in Britain for tagging adult fish. It consists of a small sealed plastic cylinder containing a printed message. It was attached to the fish by means of a bridle of soft stainless-steel wire. In all cases, hypodermic needles were used to facilitate the passage of the wires through the fish. A single needle was employed in the English and Norwegian techniques, a double needle in the Swedish method. The English and Norwegian workers attached the tag to the base of the anterior end of the main dorsal fin, so that the tag is carried on a loop above the back of the fish. The Swedish workers attached the tag to the body of the fish immediately below the dorsal fin. Thus, with the English and Norwegian methods, a small loop of wire extends over the back of the fish, whereas with the Swedish method there is no such loop. The Norwegian and Swedish workers anæsthetize the smolts with a 2 per cent solution of urethane for the tagging operation. The English workers do not normally use anæsthetics, but the fish are tagged in running water using a special holding block.

In Norway, more than two thousand smolts were tagged by the three different methods at the Lundamoen Hatchery near Trondheim. The fish were all released into the Gaula River. In Sweden, the production of electricity is based almost exclusively on the utilization of water-power, and a series of dams is being built on the main salmon rivers flowing into the Baltic Sea. The effect of these installations would be to destroy large areas of natural spawning grounds for salmon. The seriousness of such a situation would appear even more acute when it is realized that the particular value of the Baltic salmon fishery lies in its complementary relationship to the very important herring fishery in these waters. It has been decided, therefore, to substitute for the natural spawning grounds a system of hatcheries and rearing stations whereby the run of salmon can be maintained artificially by the annual release of a sufficient number of hatchery-reared smolts. In order to discover whether this system could be worked economically the Swedish authorities have tagged large numbers of artificially reared smolts during recent years.

A comparison of Swedish and English tagging methods was carried out at three stations on the east coast. The first batch of smolts was tagged at Galtstrom just south of Sundsvall. Fish reared at this particular station have normally produced a very high percentage of recaptures. The smolts were larger than normal, averaging 16–18 cm. in length and in excellent condition. More than four thousand smolts were tagged at Galstrom and all the fish were released into the nearby River Ljungan.

Another collection of smolts was tagged at Bergeforsen, near the mouth of the Indalsalven, one of the large rivers flowing into the Gulf of Bothnia north of Sundsvall. Here is situated one of the largest Atlantic salmon hatchery and rearing stations in the world. By means of a device consisting of batteries of plastic trays, more than two and a half million salmon eggs can be brought to the 'eyed' stage in quite a small room. The rearing station is constructed for the production of about four hundred thousand smolts of salmon and sea trout reared for two or three years. About 1,200 smolts were tagged at Bergeforsen and the fish were released into an artificial channel from which they could migrate into the main river at any time.

The third batch of smolts were tagged at Lulavan, situated on the Lule älv near the port of Luleå in Northern Sweden. The installation at Lulavan was merely a tagging station; but the history of the rearing of these smolts was most interesting. Although the salmon ova were from the north, the fish had been reared at Munka-Ljungby on the west coast of southern Sweden, where growth was more rapid. At the smolt stage, the fish had been transported back to the north by road tanker, a distance of 1,600 km. More than six hundred smolts were tagged at Lulavan and the fish were released into the main river.

In the spring of 1960, it is expected that Scottish, Swedish and Norwegian workers will tag smolts in an English river. Here, the fish will not be hatchery-reared but will be tagged during their natural migration out to sea.

It is hoped that some tagged fish will return in 1960; but it is clear that a statistical comparison of the methods of tagging employed in 1959 will not be possible until the end of the 1961 season, for only then will the major part of the 1959 smolt crop have been harvested.

RESEARCH METHODOLOGY AT THE LONDON SCHOOL OF ECONOMICS

By Prof. M. G. KENDALL

Director of the Research Techniques Division

RESEARCH techniques in the social sciences grew up in a very haphazard fashion; and some of them are so rudimentary that they can scarcely be said to have developed at all. After the Second World War it was plain that, if effort was not to be misdirected and wasted, some systematic assault on problems of methodology in the social sciences was necessary. With the aid of a grant from the Nuffield Foundation the Research Techniques Division at the London School of Economics and Political Science was set up to study such problems. It has no precise terms of reference and ranges over a wide field; but, broadly speaking, it is concerned with the gathering and analysis of information and the testing of scientific hypotheses in economics, sociology, social psychology and related fields.

The Division began with a grant of £2,000 a year, a part-time director, a secretary and two research assistants. At the present time, having just celebrated its tenth birthday, it has a budget of about £30,000 a year and a staff, full-time or part-time, of more than thirty. These figures will probably increase by 50 per cent over the next two or three years. Most of the funds come from outside sources. Some of the staff are full-time research officers, others are teaching members of the School staff who are associated with particular projects and others again are outside consultants. The Division has its own computing unit and library.

Methodology of Social Surveys

The elicitation of social and economic facts is itself a complicated subject. It may involve the setting up of new systems of scale or measurement unknown to the physical sciences. Even the 'mere' collection of data involves extensive methodological study, especially in the field of social surveys. From the planning of a survey, through the design of the questionnaire, the selection of the sample, the handling of the interview situation, the coding of responses and the final analysis, there lies a long chain of procedure which can introduce error at almost any point along its length. The Division carries out studies of the nature and extent of such errors in order to devise methods of reducing them and of validating the final results. It has, for example, published studies of the sampling problems involved, of the effect of using amateur interviewers, of coding errors and of the way in which response varies with the type of question asked.

More recent studies embarked upon cover the adequacy of mail questionnaires, memory bias in respondents and the characteristics of persons who volunteer for panels. On the sampling side, although the drawing of samples of human beings in the United Kingdom is now fairly well understood, there remains a number of intractable problems for study: the sampling of rare events, the sampling of firms or retail shops, and, overseas, the sampling of migrant populations or under-developed areas.

Dynamic Economics

Many natural scientists who have taken their interest in economics so far as to read a text-book must have wondered whether it is not possible to reduce the subject to the much more formal lines with which they are familiar in their own discipline. It is not, I think, true that economics can be 'turned into a science' in the sense that the methods of the natural sciences can be taken over unchanged and applied in a new field. But I believe it to be true (and this belief forms the starting-point of the Division's work on economics) that with suitable new techniques or adaptations of old ones the behaviour of economic systems is capable of far more exact study than has been attempted in the past. Under the inspiration of Prof. A. W. Phillips, and with the help of a substantial grant from the Ford Foundation, the Division is engaged in a large-scale attack on this problem.

The first requirement is to bring the postulated relationships of economics to an explicit form for quantitative study—to write down the equations. This is itself far from easy. The second problem is to write down the model of the system and to investigate its behaviour. The third stage is to fit such models to real life, which involves intricate problems of estimation and testing of hypotheses. The final stage is then to use such models in the regulation of economic systems.

It is particularly interesting that the main stimulation for such work has been furnished by electrical engineers, who have realized the formal similarity between economic systems and the feed-back networks of control engineering. The economic problem, of course, is more complicated, especially in regard to the amount of random variation and unknown time-lags to which economic systems are subject. The Division has been working in this field for several years, and has now reached the point where most of the economic relationships can be formulated, the estimation problems solved and the numerical computations carried out on an electric computer. The properties of artificial models are now being studied in preparation for the next phase, which is the study of actual portions of the economy.

Operational Research

Operational research—the science of making the best of limited resources in complex man–machine situations—is a comparatively new subject in both emergence and scope. With the aid of a small grant from the Department of Scientific and Industrial Research, the Division has spent two years in self-education, preparing bibliographies and running a fortnightly seminar attended by operational research workers from outside the School. It is now proceeding with research studies on some of the methodological problems involved in such topics as linear programming and queueing theory, and members of the Division are engaged in actual operational research for certain firms. One collateral development has been the setting up of systematic courses at the London School of Economics for postgraduates drawn from industry. It is by now quite plain that this side of the Division's work will expand substantially in the years to come.

Research on Statistical Method

A great many problems coming to the Division's attention are necessarily of a statistical character, and attempts are made to solve such theoretical statistical problems as arise. The work covers a very large field. At the mathematical end, for example, it has included the tabulation of the distribution of the characteristic roots of a random-dispersion matrix. A considerable number of studies have been published on distribution theory, estimation and inference, the theory of statistical relationship, time-series and stochastic processes. Such work, though in the main theoretical in character, usually stems from problems of analysing complicated and imperfect data such as arise in multivariate systems.

Bibliographical Work

A great deal of work within the Division's sphere of interest, as in scientific fields generally, is concerned with ascertaining what is being done elsewhere. A number of individual bibliographies have been published, for example, on queueing theory and on the life testing of industrial equipment. Some special studies have also been undertaken. For example, a "Dictionary of Statistical Terms" has been prepared on behalf of the International Institute of Statistics and Unesco; a new *Journal of Statistical Abstracts* has been founded; and the Division is on the point of going to press with the first volume of a comprehensive bibliography of papers on statistical method and probability from the sixteenth century up to the end of 1958 which will ultimately comprise about 25,000 titles.

Team Work

It is a characteristic feature of much of the Division's work that its problems require collaboration between workers in several different fields. Problems of survey research, for example, need mathematicians and statisticians at the sampling stage; psychologists at the interview stage; numerical analysts and statisticians at the summarizing stage; and sociologists or economists at the interpretative stage. Dynamic economics requires—in addition to economists—electrical engineers, numerical analysts and mathematicians. The members of the Division are, in consequence, drawn from all sorts of disciplines, and it frequently calls on the wide resources of the teaching staff at the London School of Economics as well as on those who are formally attached to it. The consequent interactions have done much to contribute to the Division's development and, I hope I may say, to its successes.

OBITUARIES

Sir Henry Tizard, G.C.B., A.F.C., F.R.S.

It is often said that you cannot keep a good man down, but you only have to look at the early history of many eminent people to realize how much they owe to chance. Tizard was thirty-five before he took the step which enabled him to develop his powers to the full. I believe that it was then that he took the quite conscious decision to become a V.I.P. He certainly achieved his greatness by his own efforts.

Tizard's forebears were all connected with the sea in some way or another and he, himself, was destined for the Navy, but failed because of eyesight. His mathematics gained him an exhibition at Westminster School, and at the outbreak of the First World War he was a Fellow of Oriel College, Oxford, having got there by way of a first-class degree in natural sciences at Magdalen, a year at Berlin under Nernst and two years at the Davy Faraday Laboratory of the Royal Institution.

When the War actually broke out, he was in Australia attending the meeting of the British Association. He returned as quickly as he could and joined the Royal Garrison Artillery, where he got himself into some difficulties owing to his highly unorthodox methods of training recruits. This, in fact, was not really his 'cup of tea' at all and he quickly succeeded in getting transferred to the Royal Flying Corps By 1917 he was captain-in-charge of all experiments on aeroplanes at Martlesham Heath and was afterwards appointed as deputy to Bertram Hopkinson at the headquarters of the Ministry of Munitions. He carried on after Hopkinson had been killed in August 1918 until he was demobilized in the spring of 1919, when he returned to Oxford.

His experiences during the War had led him to realize the immense importance of the application of science to military affairs. He decided that he would never be outstanding as a pure scientist, and Oxford, therefore, did not give him the scope that he needed to develop his talents. Towards the end of 1920 he joined the Department of Scientific and Industrial Research, and in 1926, at the age of forty-one, became secretary of the Department in succession to Sir Frank Heath. In the same year, he was elected a Fellow of the Royal Society.

In 1929 he was appointed rector of the Imperial College of Science and Technology—a post which he held for thirteen years. He did, in fact, a very great deal for the College, but, during this period, he did a great deal more in other directions.

Ever since the First World War, Tizard had maintained his interest in aeronautics. He had been chairman of the Royal Aeronautical Society in 1924, and in 1933 he was appointed chairman of the Aeronautical Research Committee—a post that he held for ten vitally important years. However, the work for which I shall always give Tizard the highest marks in that period was the job that he did as chairman of the Committee for the Scientific Survey of Air Defence which started work at the beginning of 1935. Tizard's colleagues on this body were originally A. V. Hill, P. M. S. Blackett and H. E. Wimperis, with A. P. Rowe as secretary. I shall always believe that this body, and particularly Tizard himself, were the people who made it possible for Watson-Watt to develop radar, which was the biggest contribution to the winning of the Second World War. You cannot read the accounts of the development of radar written by such varying authorities as A. P. Rowe, Lord Swinton and Watson-Watt himself without coming to the conclusion that it was Tizard's drive from the outside which ensured that radar was developed at such rapid speed—and not only developed, but also deployed in a usable form.

As the War progressed, Tizard served in the Ministry of Aircraft Production and also as the first—and last—external civilian member of the Air Council. In August 1940 he led a British mission to the United States with the object of disclosing all our scientific secrets. He took with him in his pocket a sample of the magnetron—the thermionic device, perfected in Britain by Randall and Boot, which really made radar work. One American historian said of this visit: "When the members of the Tizard mission brought the magnetron to America in 1940, they carried the most valuable cargo ever brought to our shores. It started the whole development of micro-wave radar and constituted the most important item in reverse lease-lend". In the years after the War, when information on American military research was hard to obtain, Tizard was not slow to recall his war-time mission.

In 1942 Tizard resigned from the Ministry of Aircraft Production and the Air Council to become president of Magdalen College, Oxford; but, although he now had no formal Government appointment, he still continued to advise informally on various scientific problems, and in 1943 he went out to Australia to advise the Australian Government. It was during this trip that he bearded General MacArthur in his den and shattered the morale of the General's aides by flatly refusing to regard him as anything but an equal. Incidentally, he also won a case of sherry off the General by a bet on the length of the War.

By 1946 Tizard was sixty-one. He was very comfortably ensconced as president of Magdalen and it looked as though the excitements were over. His greatest work was, in fact, still to come.

One of the major lessons of the Second World War was the vital necessity to apply science to all forms of Government activity, and this could only really be done provided the right type of scientist was brought into full collaboration in both the formation and implementation of policy. The Services learned this lesson very thoroughly indeed during the War and, as a result, the old Deputy Chiefs of Staff Committee was replaced by a new body in the Ministry of Defence known as the Defence Research Policy Committee. The Committee consisted of those responsible in the Service Departments and the Ministry of Supply, both from the operational and from the scientific angle, for the formulation of requirements for new weapons and for research and development. Its chairman was to be a scientist of high standing appointed for a period of years. At the same time, on the Civil side of Government, a committee known as the Advisory Council on Scientific Policy was also set up. Tizard was persuaded to assume the chairmanship of both these bodies; and, although from 1946 he served full-time in the Ministry of Defence, he gave a great deal of attention to the work of the Civil Council.

Between 1946 and 1950 Tizard laid the real foundations of co-operation at the top level between the scientist and the military authorities. His own position and effectiveness did much for the recognition in other fields of the need for, and value of, scientific advice. I do not believe there was any other person who could have done this with anything like comparable success. For one thing, in spite of the fact that neither he nor anybody else regarded him as an outstanding pure scientist, his standing in the scientific world was extremely high. Even by 1946, five universities had awarded him honorary degrees, and in subsequent years five more followed suit. For another, he had shown, in the days before the Second World War, his capacity to see what was important, from the national point of view, to develop and, perhaps even more, the ability to get other people in high places to accept his view. He inspired—and in this he was almost unique among the leading scientists of the day—immense respect and confidence among officers of all the Fighting Services. He had a very genuine appreciation of, and sympathy with, their problems and they all knew he wanted to help.

He dominated any committee of which he was chairman, not—as so many other people try to do—by talking all the time, but by his skilful appreciation of the characteristics of the people sitting with him and of the appropriate moment at which to intervene. Sometimes, these interventions took the form of an exhibition of bad temper. Most people thought this was spontaneous; but, in point of fact, it was most carefully rehearsed, as those who had to brief him for the meeting well knew. In those days, his moments of real anger were quite rare, and they almost invariably arose out of his unceasing warfare with what he regarded as administrative stupidity.

He was, perhaps, at his most impressive when presiding over the periodic meetings of the Commonwealth Advisory Committee on Defence Science, to which scientists and serving officers came from all over the Commonwealth. Here, he inspired a slightly awed but affectionate respect. He was, of course, a brilliant conversationalist, and the entertainments which accompanied these Commonwealth meetings gave him opportunities which he seized to the full.

He was on excellent terms with the Chiefs of Staff, particularly in the earlier days. As time went on, however, he began to be regarded as the 'Great Man', and his visits to the Chiefs' meetings became rather more formal occasions. There was, in fact, something rather magisterial about his manner, especially on any formal occasion. Even on an informal occasion, he was not a man with whom one took undue liberties. Nevertheless, to those who worked with him closely, he was a very real friend and by no means difficult.

In 1950 his health began to fail and by doctor's orders he had to slacken off a great deal. He did not take kindly to this change, but there was no doubt that he began to get tired rather quickly and then became a little bad-tempered. He recognized this, however, and I can only remember one occasion which had unfortunate results. By 1952, Tizard had begun to lose some of his confidence in himself. He thought that his health had deteriorated to such an extent that his useful working life was over, and he therefore resigned from the public service. There is no doubt that a measure of the old zest and vitality had gone out of him.

He was not, however, a man who could be idle, and for the remainder of his life he occupied himself as a director of Glaxo Laboratories, Ltd., and other public companies. In spite of many attractive offers, he refused to join any commercial organization primarily concerned with the Defence effort. He took the view—and I am sure rightly—that he had been in far too central a position in the defence field to allow him to make his special knowledge available to a single company engaged in such work.

His health improved appreciably after he retired, and right up to the day of his death he was the most delightful and inspiriting dinner companion. A typical form of activity into which he entered with all his usual enthusiasm was the year he spent in 1955–56 as Prime Warden of the Goldsmiths' Company. I am sure the Company benefited from his wisdom.

No account of Tizard would be complete without some reference to his quarrel with Cherwell. This originated in 1936 over the Committee on the Scientific Survey of Air Defence, and eventually got so bad that the two men could not endure in silence each other's presence in the same city. This, indeed, was the only matter on which I ever found Tizard really unreasonable, but Cherwell was worse. In fact, in this matter, both these eminent gentlemen behaved like a couple of spoiled children. The tragedy of it was that this quarrel prevented Tizard gaining the confidence of Winston Churchill when the latter returned to power in 1950.

By any standards, Tizard was a great man who made a large contribution to the nation's affairs. He had a very real foresight and was rarely proved wrong. I am still waiting for someone to take seriously the warning which he issued towards the close of his presidential address to the British Association in 1948. He knew little about agriculture in detail, but, as with all the other subjects he touched, he had a wide view of the necessities. "I shall predict", he said, "that unless the prevention of disease among plants and animals and all other scientific problems of the supply of food are studied on the same kind of scale by men of similar calibre as are the problems of human health, chaos and misery will result". How right he was.

F. Brundrett

Dr. Mary D. Waller

Dr. Mary Désirée Waller, who died at the age of seventy-three on December 11, was widely known for her precise and beautiful work on vibrating plates and as an outstanding teacher of physics. She came of distinguished scientific ancestry, her father being Augustus Désiré Waller, who first showed that the electric currents set up by the beating of the human heart could be recorded, and her grandfather Augustus Volney Waller, whose name is commemorated in 'Wallerian degeneration'.

Educated at Cheltenham and Bedford College for Women, as a young woman she was appointed demonstrator in the Physics Department of the London (Royal Free Hospital) School of Medicine for Women, a Department of which she later became head and in which she continued her research after her retirement in 1947. It was in 1932 that she first came into prominence by her discovery that metal plates could be thrown into regular vibration by the suitable application of a block of high-density carbon dioxide. It shows great scientific percipience that her discovery derived from the fact that an itinerant vendor of ice-cream had directed her attention to the way in which a bicycle bell rattled when in contact with ordinary solid carbon dioxide.

With this solid carbon dioxide technique, the mode of action of which she explained, she carried out extensive and precise studies of the modes of vibration of metal plates of square, rectangular, circular and elliptical form, illustrated by beautiful photographs, the series recording the vibrations of a square plate being particularly striking. Her last published work included some interesting observations on the ridges formed by particles of different size and shape in the sound field between a vibrating plate and a parallel horizontal surface. At the time of her death she had nearly completed a book dealing with her work on vibrating plates, the appearance of which has been announced by the publisher. It is to be hoped that a colleague will finish the work and see it through the press.

Dr. Waller was a woman of great integrity and kindliness, whose brightness and charm made her a welcome figure in scientific, and other, circles. As an accomplished teacher she endeared herself to generations of students in her Department. She was devoted to the subject that she made her own, but her interests were wide and she was a delightful conversationalist. She lived for many years with her friend, Dr. Bertha Turner, at a charming house in the neighbourhood of Regent's Park, in which she died.

E. N. da C. Andrade

Mr. Cyril L. Collenette

Cyril Collenette, who died suddenly on November 2 at the age of seventy-one, devoted most of his life to the study and service of natural history. His boyhood days were spent in the stimulating surroundings at Woodford, then a country parish in the heart of Epping Forest, and this early bent for the pursuit of Nature's secrets and offerings was never to leave him. He became a world-wide traveller naturalist in such places as Malaya, French Guinea, the Matto Grasso and British Somaliland, making valuable additions to collections, especially of insects.

Collenette's main life's work began and ended at the British Museum (Natural History), South Kensington, as an associate and world authority on the large family of moths, the Lymantridae. Apart from his museum work, he was a keen spare-time botanist and bird observer, ever willing to pass on his experiences and recordings to such bodies as the British Trust for Ornithology (he was one of its earliest ringers), and the London Natural History Society (a member since 1907 and one-time president). He was on the Committee for the Birds of the Royal Parks, as well as on that of the London Natural History Society during the compilation of its book, "Birds of the London Area".

His own books include "A History of Richmond Park", written during 1937 when living at Richmond, and "Sea-girt Jungles", written on his return from a long Pacific sea voyage on the *St. George*, a sailing vessel which visited such places as the Marquesas, Easter Island and the Galapagos. He told me that this was one of the most exciting and rewarding episodes of his natural history career.

His colleagues at South Kensington will miss their tall and friendly companion, and all who sought out his advice and friendship will mourn an ever-willing helpmate and kindly friend. Alfred Leutscher

NEWS and VIEWS

Vice-chancellor of the University of Monash: Prof. J. A. L. Matheson

PROF. J. A. L. MATHESON sailed for Australia before Christmas to take up his appointment as vice-chancellor of the University of Monash, Melbourne, and to begin his exciting and responsible task of building a new University. Matheson, who was educated at Bootham School, York, succeeded the late A. H. Gibson as Beyer professor of engineering in the University of Manchester in 1951, having been lecturer in civil engineering in the University of Birmingham from 1938 to 1946 and professor of civil engineering in the University of Melbourne from 1947 to 1950. During his tenure of the Beyer chair at Manchester, Matheson re-organized the engineering courses and planned new laboratories to house the post-war expansion. In addition, he played an important part in the wider field of university building and planning. He directed research into various aspects of theory of structures, including the use of scale-models and the load-carrying capacity of rigidly jointed triangulated steel frames. It was largely due to his guidance that so much has been done in Manchester to further the use of electronic digital computers for the analysis of complex structural problems. His work culminated earlier in the year in the publication of his book, "Hyperstatic Structures", which is impressive for its scope and scholarship.

Civil Engineering at Manchester: Prof. M. R. Horne

DR. M. R. HORNE, lecturer in the Department of Engineering, University of Cambridge, has been appointed professor of civil engineering in the University of Manchester and will take up the post next summer. Dr. Horne was born on December 29, 1921, and was educated at Boston Grammar School and Leeds Grammar School before going to St. John's College, Cambridge, in 1939. He had a distinguished academic career, obtaining honours and the Archibald Denny Prize in the Mechanical Sciences Tripos, 1941. He was awarded the John Winbolt Prize for an essay on an engineering subject in 1944. During 1941–45 Horne worked for the River Great Ouse Catchment Board as an assistant to the District Engineer, Bedford, surveying and carrying out reconstruction of weirs and sluices. He returned to the Department of Engineering, Cambridge, in 1945, joining the team which was then being assembled to continue the work, started before the War in Bristol, on the plastic behaviour of steel structures. He obtained the Ph.D. degree in 1950. In 1951 he was appointed an assistant director of research on the introduction of the postgraduate course of instruction on structures and materials, the first such course to be introduced by the Cambridge Engineering Department. Horne transferred to the post of University lecturer in 1957, in which year he was elected a Fellow of St. John's College. In the fifteen years that Horne has been back in Cambridge he has played a prominent part in the development of the theory of the plastic behaviour of structures and of the design method based on it.

Director of the Forest Products Research Laboratory: Dr. F. Y. Henderson, C.B.E.

DR. F. Y. HENDERSON, who retires from the directorship of the Forest Products Research Laboratory, Princes Risborough, in October, was reader in timber technology at the Imperial College of Science and Technology. Initially interested in plant physiology, he took over Percy Groom's Sub-department of Technology of Woods and Fibres; the elementary text-book on wood technology which he wrote then proved specially popular with those in the timber trades. Henderson's tenure of the directorship marks a period in the history of the Forest Products Research Laboratory. He took over in 1945, when many relatively unknown woods were beginning to replace well-tried ones, and these needed investigation and assessment in relation to the traditional timbers; new and little-known insect and fungal pests claimed attention; plywood had developed enormously and the Laboratory played its part in research on such laminated wood. This work, and other aspects, like wood bending, machining and adhesives, might have been mentioned—it was Henderson's task to co-ordinate and guide. Moreover, the past few years have seen the enormous expansion of co-operative work with the Forestry Commission and the beginning of research on the pulping of home-grown timbers. The steady flow of important bulletins from the Laboratory emphasizes the volume of varied work carried out there since the War and, during this time, trade and private inquiries have occupied much of the time of the staff. Henderson's retirement marks the end, more or less, of this period. Relieved of most of the inquiry work, his colleagues have more time for the fundamental work for which the laboratory is well equipped. Moreover, reconstituted wood products, like hardboards and laminated wood, are replacing solid timber in many of its traditional uses and presenting their own special problems to the Laboratory.

Mr. H. Wooldridge, O.B.E.

MR. HENRY WOOLDRIDGE, who will succeed Dr. Henderson, has been a member since its formation of the Steering Committee of the Forest Products Research Laboratory. He has spent most of his career at the headquarters of the Department of Scientific and Industrial Research, where he is at present head of the Stations Division, and as such is responsible for liaison with all the Department's laboratories. Previously, he was deputy establishment officer in the Department, and before that he served two secretaries of the Department, Sir Frank Smith and Sir Edward Appleton, as private secretary. Mr. Wooldridge joined the Department in 1935 from the British Association for the Advancement of Science, of which he had been assistant secretary for five years. He was educated at Reading School and King's College, London.

Royal Society and Nuffield Foundation Commonwealth Bursaries

AWARDS under the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme have been made as follows: Dr. R. N. Brothers, senior lecturer in petrology, University of Auckland, to enable him to examine at the Imperial College, London, the application of crystalline and deformation theories for certain New Zealand ultrabasic rocks to a group of related rocks which occur in Great Britain, for a year from November 1959; Dr. J. W. Clark-Lewis, senior lecturer in organic chemistry, University of Adelaide, to enable him to continue a study of the chemistry of natural products, with particular reference to the stereochemistry of flavan derivatives, at the Imperial College, London, for seven months from October 1960; Dr. A. W. Crompton, director of the South African Museum, Cape Town, to enable him to study mammalian palæontology at Cambridge and the British Museum (Natural History) for four months during 1960; Dr. J. C. Gould, senior lecturer in bacteriology, University of Edinburgh, to enable him to extend his studies of staphylococcal infections and make comparative studies in an African community, in Nigeria, during May–September 1960; Prof. K. R. L. Hall, professor of psychology, University of Bristol, to enable him to carry out a field-study of behaviour and social organization of wild baboon groups in differing environments in South and South-West Africa, during July–September 1960; Dr. L. M. Jackman, lecturer in organic chemistry, Imperial College, London, to enable him to investigate hydrogen bonding in organic molecules by nuclear magnetic resonance spectroscopy, at Adelaide, during July–October 1960; Prof. D. O. Jordan, Angas professor of physical and inorganic chemistry, University of Adelaide, to assist him to visit University College, London, and the Royal Cancer Hospital, London, during February–September 1960, in order to study new techniques and particularly those concerned with the structure, behaviour and functioning of biological macro-molecules; Prof. H. Kleerekoper, professor of zoology, McMaster University, to assist him in completing during the summer of 1960 an investigation of bottom sediment cores of Lake Moneague, Jamaica, for which a bursary was awarded to him in April 1958; Mrs. Beryl E. March, instructor and research associate, Department of Poultry Science, University of British Columbia, to assist her to visit Cambridge during May–August 1960 in order to study methods of evaluating the nutritive value of fish meals; Dr. E. H. Mercer, of the Chester Beatty Research Institute, London, to enable him to carry out an electron microscopic study of cell division and differentiation in plants, at Sydney, during February–July 1960.

The Liverpool Geological Society

THROUGHOUT the first three days of 1960 the centenary celebrations of the Liverpool Geological Society, happily combined with the eighth Inter-University Geological Congress, attracted an enthusiastic gathering of more than two hundred geologists. The theme of the meetings was "Recent Advances in Geology", and each of ten lectures by speakers from British and foreign universities gave rise to spirited discussion. The Society has now published the text of these addresses in a volume of more than three hundred pages which is a fine contribution to geological literature (*Liverpool and Manchester Geol. J., Centenary Issue*: price 20*s*.). In it, T. S. Westoll reviews recent studies on the palæontology of fishes: G. Voll, in a sixty-page paper, summarizes the latest work in the field of petrofabrics; S. I. Tomkeieff describes sources of information on the geology of the U.S.S.R.; L. M. J. U. van Straaten writes on deltaic sedimentation; R. G. Mason on geophysical investigations of the sea floor; W. S. Mackenzie on experimental studies in petrology; W. C. Krumbein on numerical data in geology; C. F. Davidson on radiogeology and geochronology; and R. H. Cummings on advances in micropalæontology. An essay by W. E. Swinton tells the history of *Chirotherium*, the reptilian foot-print found in the Triassic rocks of Cheshire (long believed to be the hand-print of a mammal) which is reproduced on the seal and medal of the Society. Liverpool geologists have done well in sponsoring this readable review of present knowledge in some of the most active branches of earth science.

Uranium in South-West England

THE reconnaissance survey for uranium, carried out by the Atomic Energy Division of the Geological Survey during the past two years, is now virtually complete. Seventy new occurrences of uranium have been found during the course of operations which have included an aerial survey of Cornwall, Devon and much of Somerset, as well as surface mapping, excavating and drilling at promising localities. No deposit of economic importance has been discovered, and it is concluded that if any are present they are covered to such a depth with soil or overburden that they are unlikely to be detected by existing instruments. Although no deposit estimated to contain more than 5 tons of uranium oxide has been found as a result of this survey, the South-West of England uranium province has served for many years as an ideal testing ground for British geological electronic equipment, which is now used extensively throughout the world. The study of uranium occurrences in Cornwall and Devon, started in 1945, has played an important part in the discovery of uranium in the Commonwealth, while recent work has contributed considerably to the development of aeroradiometric surveying techniques.

Scientists and Engineers in American Industry

THE U.S. National Science Foundation has stated that American business firms employed about 780,000 scientists and engineers in January 1959. About 35 per cent of the total were engaged in engineering and scientific research and development activities. Scientists and engineers in the industry sectors included in the current survey are estimated to represent approximately two-thirds of the scientists and engineers employed in the United States. The other third are employed in government agencies, educational institutions, non-profit organizations, and self-employed. Industries employing the largest groups of scientists and engineers in January 1959 were aircraft and parts, electrical equipment, and chemicals and allied products. Each employed more than 75,000 scientists and engineers; combined, they employed one-third of the total number of scientists and engineers in private industry and approximately half the scientists and engineers engaged in the performance or administration of research-and-development activities in private industry. Each of two other industries employed more than 50,000 but less than 75,000 scientists and engineers: machinery (except electrical) and engineering and architectural services. Next in size, in terms of scientific and engineering employment, were construction, fabricated metal products and ordnance, primary metals, and motor-vehicles and equipment; each of these industry groups employed more than 30,000 but less than 50,000 scientists and engineers. Employment of scientists and engineers in private industry was about 4 per cent higher in January 1959 than in January 1958. Engineering employment increased from about 605,000 in January 1958 to 630,000 in January 1959. The number of scientists employed in private industry increased from about 145,000 in January 1958 to 150,000 in January 1959.

British Digital Computer Information Centre

The National Centre of Information on Automatic Programming of Digital Computers has been established by the Department of Mathematics of the Brighton Technical College in response to a recommendation of the first National Conference on Automatic Programming held in Brighton in April 1959. The purpose of the Centre is: to establish and maintain a comprehensive library of publications; to publish, in conjunction with Pergamon Press, Ltd., an annual review of automatic programming; to provide a 'clearing house' for information and inquiries on automatic programming; to organize small working conferences on particular aspects of the subject; and to maintain permanent contact with organizations in all other countries concerned with such matters. An advisory committee to assist the work of the Centre has been established and includes Dr. A. D. Booth (University of London), Mr. R. A. Brooker (University of Manchester), Mr. P. V. Ellis (International Computers and Tabulators, Ltd.), Dr. S. Gill (Ferranti, Ltd.), Dr. J. Howlett (United Kingdom Atomic Energy Authority), Dr. R. J. Ord-Smith (Standard Telephones and Cables, Ltd.), Mr. C. Robinson (English Electric Co., Ltd.), Mr. Christopher Strachey, Mr. A. E. Taylor (Remington Rand, Univac), Mr. J. H. Wensley (Computer Developments, Ltd.), and Mr. M. Woodger (Mathematics Division, National Physical Laboratory), together with the following as corresponding members: Dr. Grace Hopper (Remington Rand, U.S.A.), Dr. L. Luckaszewicz (Mathematical Machines Laboratory, Polish Academy of Sciences), and Prof. H. Rutishauer (Institute of Applied Mathematics, Zurich). Further information can be obtained from the organizing secretary, Mr. Richard Goodman, Department of Mathematics, Brighton Technical College.

Hospital Morbidity Statistics in Great Britain

A further contribution to the study of morbidity has recently been published by the General Register Office (The Registrar General's Statistical Review of England and Wales for the Year 1955. Supplement on Hospital In-Patient Statistics. Pp. vii+206. London: H.M. Stationery Office, 1959. 10*s.* 6*d.*). This volume summarizes the results of the hospital in-patient inquiry for 1955. This inquiry, which is steadily becoming more comprehensive, is expected to cover virtually the whole of the discharges of in-patients from hospitals in Britain by 1957; but in 1955 the hospitals that participated did so on a voluntary basis. Nevertheless the principal specialities seemed to be represented in close correspondence with the national figures, and the inquiry was fully representative of two hospital regions, East Anglia and Wales, for which special statistics are given. The statistical unit used in the inquiry is the discharge of an in-patient from a hospital, and the principal tables in the volume show the number of such discharges in various age and sex groups, and in different regions, by principal condition diagnosed. The number of deaths in hospital is shown separately, and there are data dealing with the duration of stay and the waiting period before admission to hospital. Special tabulations deal with children in hospital and maternity cases. Teaching and non-teaching hospitals are distinguished throughout. While hospital morbidity statistics are not a wholly reliable guide to morbidity, they can, as the report indicates, be of considerable assistance in the study of the mass aspects of disease, and the data will also be of considerable value to the hospital administrator. It is to be hoped that future tabulations will give information about the socio-economic status of the patients discharged. The appearance of this volume provides a valuable addition to our knowledge of the functioning of the National Health Service.

Transvaal Museum

After a lapse of four years it is fortunate that it was possible once again, during July 1959, to publish the *Bulletin of the Transvaal Museum*. A topical article on "Excavating Ape-Men", by Mr. J. T. Robinson, describes the cave limestone in which such remains are found. The grid system of excavation is described and all bone is treated with 'Glyptal' cement immediately after it is removed from the breccia. Afterwards a 10 per cent solution of acetic acid is used to free the bones from the surrounding matrix.

Musical Rites

Certain hard igneous rocks ring when struck and the note obtained depends on the dimensions of the rock itself. By careful shaping different notes can be obtained and a sort of 'glockenspiel' created. There is a decorated rock-shelter in Nigeria where such a 'glockenspiel' occurs to which parties come to be married, their faces being first carefully whitened. Dr. B. D. Malan describes just such a rock gong site in the Parys district of the Orange Free State in the *South African Journal of Science* (55, No. 2). It is well known that music plays a prominent part in the lives of many primitive folk; these gongs are very interesting and the resulting 'music' not at all unpleasant.

The Commonwealth Scholarship Commission

The Earl of Scarbrough has been appointed chairman of the Commonwealth Scholarship Commission in the United Kingdom. The Commission is to be set up under the Commonwealth Scholarships Act, 1959, recently passed by Parliament, to administer the Commonwealth Scholarship and Fellowship Plan in Britain. This Plan was worked out by the Commonwealth Education Conference at Oxford in July 1959 and creates a thousand new postgraduate awards throughout the Commonwealth. Of these, the United Kingdom will contribute five hundred scholarships and fellowships tenable in the United Kingdom at any one time.

University News: London

Dr. G. V. R. Born, research officer at the Nuffield Institute for Medical Research and departmental demonstrator in the Department of Pharmacology in the University of Oxford, has been appointed to the Vandervell chair of pharmacology tenable at the

Institute of Basic Medical Sciences. Dr. D. L. J. Bilbey, assistant professor of anatomy in the University of Toronto, and Dr. R. M. H. McMinn, lecturer in the University of Sheffield, have been appointed to readerships in anatomy tenable at King's College.

The title of professor of economics in the University of London has been conferred on Mr. B. S. Yamey in respect of his post at the London School of Economics and Political Science.

The title of reader in physics in the University of London has been conferred on Dr. D. M. MacKay in respect of his post at King's College.

Southampton

The Institution of Structural Engineers is to provide funds for the establishment of a readership in structural engineering in the Department of Civil Engineering of the University. The Institution will make available £2,000 per annum for seven years at the end of which period the Council will be responsible for the appointment.

Borough Polytechnic, London

The following appointments in the Borough Polytechnic have been made: G. Isserlis, senior lecturer in charge of the Division of Metal Science; Dr. D. B. Smith, senior lecturer in food technology; S. N. Houldsworth, lecturer in chemical engineering; Dr. B. E. Weller, lecturer in physical chemistry; Dr. H. W. Hykin, lecturer in mechanical engineering.

The Night Sky in February

Full moon occurs on Feb. 12d. 17h. 24m. U.T., and new moon on Feb. 26d. 18h. 24m. The following conjunctions with the Moon take place: Feb. 6d. 16h., Aldebaran 0·5° S.; Feb. 22d. 00h., Jupiter 5° S.; Feb. 23d. 04h., Saturn 4° S.; Feb. 24d. 07h., Mars 5° S.; Feb. 24d. 13h., Venus 4° S. In addition to these conjunctions with the Moon, Venus is in conjunction with Saturn on Feb. 7d. 11h., Venus being 0·2° N., and Venus with Mars on Feb. 17d. 03h., Venus being 1·1° N. Mercury can be seen as an evening star during the later part of the month, setting at 19h. 15m. on February 25. It reaches greatest eastern elongation on February 23. Venus is a morning star, rising about 2 hr. before the Sun at the beginning of the month. Later in the month it becomes too close to the Sun for observation. Mars is badly placed for observation, rising about an hour before the Sun. Jupiter is a morning star, rising at 5h. 00m., 4h. 20m. and 3h. 35m. on February 1, 15 and 29, respectively. It may be seen low in the south-east before sunrise; its stellar magnitude is −1·5. Saturn is also a morning star, but it is still too close to the Sun for satisfactory observation. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Feb. 2d. 19h. 49·3m., μ Psc. (*D*); Feb. 6d. 14h. 26·0m., Aldebaran (*D*); Feb. 6d. 15h. 10·0m., Aldebaran (*R*); *D* and *R* refer to disappearance and reappearance, respectively.

"Salicylate and Potassium Fluxes of Rat Diaphragm"

We regret that certain printing errors appeared in the communication by Dr. J. A. Hicklin, published in *Nature* of Dec. 26, p. 2029. In the penultimate line of the second paragraph, the word 'active' should be deleted. In the third paragraph, the second sentence should read: "Contrary to expectation the principal effect of salicylate was consistently to accelerate the *efflux* of potassium-42", and the fourth sentence of the paragraph refers to estimates of *influx*.

Announcements

The Medical Research Council has recently established the following new research units: the Blood Coagulation Research Unit, by agreement with the United Oxford Hospitals, at the Churchill Hospital, Oxford, under the part-time direction of Dr. R. G. Macfarlane; and the Environmental Radiation Research Group under the honorary direction of Prof. F. W. Spiers in the Department of Medical Physics, University of Leeds.

Following the appointment of Captain R. A. Villiers as the first director of the Scientific Instrument Manufacturers' Association of Great Britain as from October 1, 1959, it has been announced that Mr. G. L. Knight has been appointed assistant director. Mr. Knight will operate under Captain Villiers in the field of information and external activities, and will be responsible for the collection and distribution of information for the Association.

A small travelling exhibit on rocket astronomy has been lent to the Science Museum, London, until the end of February by the United States Naval Headquarters. Pictures show the launching of rockets and photographs of the Sun taken from the rockets. An actual camera which has been recovered after use in a rocket is included in the exhibit, which is explained by a recorded talking commentary.

The Institute of Electrical Engineers has announced that the Faraday Lecture will be given by Prof. M. G. Say on February 17, at the Central Hall, Westminster, and will be entitled "Electrical Machines". Further information can be obtained from the Secretary of the Institute of Electrical Engineers, Savoy Place, London, W.C.2. Admission, which will be by ticket only, is free.

An all-day meeting of the Welsh Soils Discussion Group will be held on February 3 at University College, Aberystwyth. The programme will be introduced by Mr. J. R. Thom, director of forestry for Wales, and succeeding papers will deal with forestry and soils. Further information can be obtained from Mr. J. A. Taylor, Geography Department, University College, Aberystwyth.

A Symposium on "Basic Questions in the Structure of Languages" will be jointly sponsored by the American Mathematical Society and the Association for Symbolic Logic at the Hotel New Yorker in New York during April 14–16. At the same time and place the American Mathematical Society is also organizing a two-day symposium on "Stability Problems in Hydrodynamics". Further information can be obtained for both symposia from the Associate Secretary, American Mathematical Society, 190 Hope Street, Providence 6, Rhode Island.

A course of ten lectures entitled "Reactor Fuel Element Technology" will be given in the Department of Chemical Engineering at the Imperial College of Science and Technology on Thursday afternoons during February 11–March 17. This course is designed to lay emphasis on the industrial problems of reactor fuel-element technology. The speakers will be from the United Kingdom Atomic Energy Authority. Further information can be obtained from the Registrar, Imperial College of Science and Technology, London, S.W.7.

CENTENARY OF "THE ORIGIN OF SPECIES"

SOME BOTANICAL ASPECTS

THE Conference arranged by the Botanical Society of the British Isles to celebrate the centenary of the publication of the "Origin of Species" was held during November 27–29 and was well attended by members and visitors.

The President, in his introductory remarks, directed attention to the importance of Darwin's friendship with Hooker in the development of the botanical arguments in the "Origin".

Lady Barlow enlarged on this theme, among others, in the course of a most interesting and illuminating account of her grandfather's botanical activities. She pointed out that, though Darwin had benefited greatly from his taxonomic work on Cirripedia, his work on plants was entirely of an experimental kind and laid the foundations of a great deal of the subsequent development of these branches of botany.

Prof. T. W. Böcher (Institute of Plant-anatomy and Cytology, Copenhagen) traced the development of cytotaxonomy since Darwin's time. He pointed out that though Robert Brown discovered the nucleus when Darwin was twenty-two, and when he was only thirty-nine Hofmeister discovered chromosomes, what is now called cytotaxonomy was not born until this century. He regarded Rosenberg, who in 1909 demonstrated a polyploid series in *Drosera*, as the Father of this branch of botany. Rosenberg had many distinguished pupils, among them Tackholm and Heilborn, who together with Jørgensen, Tischler, Winge and, in Britain, Ruggles Gates, Blackburn and Heslop-Harrison placed the study on a firm footing in the 1920's. Among others who played an equally important part in this early development were Clausen, Hagerup, Langlet, Percival and Senjaninova. Meanwhile, in the U.S.S.R. under Navashin another school grew up more concerned with ideograms and karyotypes than with chromosome numbers.

Both these approaches, combined with the discovery of apomixis, permanent structural hybridity and allopolyploidy by later workers, have been extremely fruitful.

Not least among the benefits which botanists have derived from the growth of cytotaxonomy is the kind of information which should deter them from, as Prof. Bocher said, "attempting species-making in groups where any cutting up into described taxa will, at most, have only local or temporary importance".

The vital necessity of combining careful taxonomic work with cytological studies was pointed out and illustrated by reference to *Campanula rotundifolia* and *Triglochin maritima*, among others. *C. rotundifolia* is a variable complex consisting of rather local diploids, usually clearly distinguished from one another but resembling tetraploids growing in the same neighbourhood, which are themselves widespread and intergrading. The variation here seems to be mostly due to structural hybridity and has so far defied satisfactory taxonomic analysis. In the *Triglochin maritima* complex, on the other hand, there is a polyploid series ranging from $2n$ to $24n$ and at least some of the members of this series have distinct morphological characters and distributions, and correspond to previously described though not generally accepted species.

After surveying recent work on genera and families, Prof. Böcher pointed out that the names cytotaxonomy, experimental taxonomy, biosystematics or synthetic taxonomy are perhaps superfluous. It might be better just to use the word taxonomy, "presupposing that all taxonomists now and in the future to the best of their ability are cyto-geno-eco-choro-taxonomists".

Prof. W. H. Camp (Connecticut) in the course of an illuminating and entertaining hour described some of the ways in which evolution is occurring in the world to-day, illustrating his lecture with examples from his own experience. During the past century biologists had paid little more than lip-service to Darwin, and it was only recently that we had obtained a real insight into the mechanism of evolution.

His own approach to the problem had been *via* population genetics, which attempts, to begin with, to discard the classical species-concept and to study either populations in the field or samples of them in cultivation. From studies of this kind series of group concepts develop which are often, though not necessarily, identical with the traditional species, and at the same time a great deal of information is obtained about evolutionary processes which are going on now and often also about those which have taken place in the past. Knowledge of the cytology and breeding systems of the plants with which he is concerned, as well as the 'taxonomic eye', are essential for the accurate interpretation of the biosystematist's observations.

The variation in morphology and ecology in American species of *Fagus* and *Vaccinium* can be explained largely by the effects of Pleistocene changes in climate which gave the opportunity for introgression between a number of distinct but homoploid species, followed by selection for particular combinations of physiological and morphological characters adapted to the various habitats available in post-glacial times. Corroborative evidence for this is provided by the fossil remains of *Fagus* in various parts of the North Temperate regions and by the variation in kind and quantity of alkaloids in the bark of different *Cinchona* populations. In the *Vaccinium corymbosum* complex the situation is further complicated by the production of both auto- and allopolyploids.

Prof. Camp went on to demonstrate the extremely rapid changes which occur in *Viola* populations in response to variations in light-intensity, humidity and other habitat factors. This is a group in which morphological and physiological variation is very great and sterility barriers almost non-existent.

Attempts at subdivision into species seem to be meaningless as there is a continual evolution of new genotypes from chasmogamous flowers and, at the same time, the abundant production of seed from cleistogamous flowers allows of rapid increase of the best-adapted individuals in a population.

In conclusion, he suggested that evolution is perhaps best regarded not primarily as the production of new species but as the genetic ability of organisms to fill the multitudinous new habitats being constantly presented to them by the changing environment. Species may then be considered as 'ephemeral nodes in the genetic reticulum' within the space-time continuum.

Prof. D. H. Valentine (Durham) spoke about evolution in *Primula* section Vernales in which there are nine species, all with $2n = 22$, and all but two, *P. veris* and *P. lofthousei*, capable of crossing with fairly good meiotic pairing in the hybrids. Most species have long peduncles and erect capsules with dry seeds but in three with short peduncles the capsules lie on the ground. Of these *P. vulgaris* has sticky ant-dispersed seeds and occurs over quite a wide area, but the other two, with dry seeds, are very local endemics, the difference being perhaps attributable to the relative efficiency of the dispersal mechanisms.

It is possible to arrange the species of this section in a series based on the ease with which they can be crossed. This does not altogether agree with the morphological sequence, and, in the absence of almost all knowledge of the genetic mechanism and physiological basis of 'crossability', it is impossible to be certain which is nearer the phylogenetic truth. It is clear that evolution in this group has been gradual and continuous and is combined with geographical and ecological isolation rather than sterility barriers. In other sections of the genus, for example Farinosae, polyploidy has played an important part.

Dr. N. Hylander (Uppsala) gave an account of some trends in modern research work on Scandinavian plants. He pointed out that a number of species previously unknown in Scandinavia had been discovered, even in the past decade, a remarkable thing in a region which has for long possessed an unusually high concentration of botanists. The possibility of perglacial survival has been the subject of many investigations, and, Dr. Hylander thought, had perhaps been rather overdone. So many species have been added to the list of survivors that the supposed nunataks now gave the impression of having been overpopulated. Endemism in the *Papaver radicatum* group, he suggested, might after all be of relatively recent origin. The ecotype concept of Turesson is an important Scandinavian contribution to botany and one which, combined with cytological work, has occupied the attention of many workers.

Variation within agamospecies has been observed in a number of plants and the basis of it investigated by Sørensen and Gudjonsson in triploids of the *Vulgata* group of *Taraxacum*. Here it has been shown that loss of one, or rarely two, chromosomes is responsible for most of the variations, and that *gigas* forms arise through polyploidy. Detailed study of the taxonomy and the method and speed of dispersal of microspecies has yielded much information about plant migrations and the age of different floristic elements.

Prof. I. Manton (Leeds), before proceeding to discuss some aspects of evolution in Pteridophyta, said how much she owed to the stimulation and instruction she had received from both Rosenberg and Prof. W. H. Lang. She then outlined some of the main aspects of the cytology of the group, pointing out that, since high basic numbers and polyploidy were frequent, it was important for cytologists to be well acquainted with the twenty-nine times table. In some tropical species of *Ophioglossum* diploid numbers greater than 1,000 occur and it is difficult to imagine the mechanism by which pairing is achieved at meiosis.

Allopolyploidy appears to be the chief means by which species have been formed, at least among Polypodiaceae in the broad sense. About 50 per cent of British ferns are known to be allopolyploids, one parent of which is often known; the other parent is sometimes to be found in N. America and most of those at present unknown will probably be found in temperate Asia when that region is better explored botanically.

From a fairly exhaustive study of the cytology of Pteridophyta in Britain, Madeira, Ceylon, Malaya and Tropical Africa it is evident that in this group polyploidy is not a response to cold, as has been suggested for angiosperms. In Ceylon and Tropical Africa 60 per cent of the species so far investigated are polyploids.

Natural hybrids occur among the ferns far more frequently than is generally recognized, but the F_1 generation is often so like one parent that they pass unnoticed. Prof. Manton estimated the number of living species of ferns at approximately ten thousand and between them at the very least five thousand hybrids occur. It is thus evident that ample opportunities exist for continued evolution through allopolyploidy.

Dr. G. D. H. Bell (Plant Breeding Institute, Cambridge) demonstrated how 'pure' cytotaxonomy was being applied to the improvement of crop plants. He made it clear that the highest taxonomic skill combined with a good knowledge of cytology and genetics, and adequate facilities, were essential for this work and that so far, even with *Triticum*, no more than a small beginning had been made.

The collection of wild relatives of crop plants from centres of genetic variation followed by a thorough study of the genetics, cytology and taxonomy of the material provide the basic information, which in *Triticum* has led to a good understanding of the genomes of the cultivated hexaploids. New amphidiploids produced, with the aid of colchicine, from crosses between *Aegilops ovata* and $6n$ wheats have enabled increased genetic variability to be introduced into this important crop plant. Resistance to *Erysiphe graminis*, for example, can be brought in from the *Aegilops* parent and promises to be valuable. A technique has recently been worked out for introducing one or two *Secale* chromosomes into hexaploid wheat through suitable hybridizations, thus giving an entirely new source of variation which may prove of practical importance.

Dr. Bell pointed out that not only was taxonomy *sensu* Bocher the basis of plant-breeding but also that the benefits were reciprocal; indeed, work of this kind could go far towards solving the problem of world food supplies.

An interesting series of exhibits illustrating recent research on the subjects of Darwin's botanical works was on view and directed attention to the variety of lines in which he was the pioneer. It is perhaps not generally known, for example, that he was the first person to use coleoptiles in the experimental investigation of phototropism.

A highly successful and enjoyable meeting concluded with a conversazione and a visit to Down House.

A full account of the Conference will be published by the Society. T. G. TUTIN

UNIVERSITY STUDENTS AND THEIR ACADEMIC ORIGINS

WITHIN the past ten years there have been several valuable studies of student performance at universities in the United Kingdom, some concerned with 'wastage', or failure to complete a course of study; some with degree of success achieved by those who did not fall by the wayside; and some (of which the survey under notice is an example) with both. A variety of factors make it difficult to compare the results of such investigations. First, they usually relate to one particular university or college, where conditions affecting initial selection of students and their subsequent academic progress may differ materially from those obtaining elsewhere. Secondly, they are often based on the intake of a particular year (differing from the year chosen in other surveys), and year-to-year fluctuations in the quality of students are believed to be considerable, at least within one college, faculty or department. Thirdly, to serve the purpose of the inquiry, success or failure is analysed in terms of a limited number of characteristics, which vary from one survey to another.

The limitations imposed by these and other factors are well brought out if the survey relating to the Queen's University of Belfast (An Audit of Academic Performance: a Study of the Prediction of Academic Success in the Queen's University of Belfast. By Michael Forster. Pp. 75. Belfast: Queen's University, 1959. 7*s.* 6*d*.) is put side-by-side with another very recent one, undertaken by the Cambridge University Sociological Society (Academic Careers of Entry of 1955). There is no need to emphasize the importance of the different setting provided by the Queen's University of Belfast as compared with the University of Cambridge for a study of academic performance. In the Queen's University case the students concerned are those who entered in the four-year period 1946–49; for Cambridge, the intake of one session, 1955–56, was taken. For the purpose of the Belfast inquiry, degree of academic success was analysed in terms of four main possible associated factors: performance in the Northern Ireland Senior Certificate Examination (the main mode of entry), age at entry, whether educated at a Belfast or a non-Belfast school, and whether a scholarship holder or not. In the Cambridge inquiry the factors selected were two in number. The first was type of secondary school attended, and here the main classification separated Headmasters' Conference, Direct Grant, Grammar and other schools from each other (but did not, unfortunately, distinguish between predominantly boarding and predominantly day schools within these categories). The second analysis involved comparing the performance of entrance scholars and exhibitioners with that of commoners.

Although few comparisons can usefully be made between two studies with such very different settings and purposes, this does not, of course, imply that they were not worth undertaking. Their value lies, to begin with, in providing a factual basis for discussion of the topics with which, individually, they were designed to deal. Is the examination, on the basis of which entrance to the Queen's University is largely determined, a satisfactory index of probable future performance? Are Cambridge colleges admitting too high a proportion of entrants from certain types of school, at the expense, perhaps, of other entrants more likely to show good academic results? Another obvious value of these surveys is that, when further investigations are made in the same universities for later years, it will be possible to identify some of the changes that have taken place. Again, each new survey makes some contribution to the methodology of work in this particular field. Finally, where a number of inquiries relate to the intake of different universities in the same year, there is at least the possibility of fruitful inter-university comparison. The Cambridge survey, for example, has taken the year used in the study of admissions undertaken by me for the Committee of Vice-Chancellors and Principals, and this is also the basis on which Prof. D. V. Glass and his colleagues are conducting a large-scale follow-up inquiry which should throw considerable further light on the social factors influencing academic success among students at British universities.

R. K. KELSALL

PLANT–ANIMAL FOOD CYCLES IN THE SEA

MICROSCOPIC phytoplankton floating passively in the sea have proved a suitable field for the techniques of population dynamics. Gordon Riley and others have shown that when populations of plants, and also the herbivores that graze on them, are considered in terms of their content of organic carbon, it is possible to predict roughly the varying quantities in different areas in terms of the changes in the physical environment. The problem, however, from the point of view of fisheries studies, is that only one part of this generalized organic matter may be relevant. Thus, herring will feed on copepods but not on salps, both of which graze on the phytoplankton. In this way an area of high primary production is a necessary but not a sufficient condition for a commercial fishery.

A paper by Dr. D. H. Cushing, of the Fishery Laboratory at Lowestoft, is of interest because in a study of the organic production in the southern North Sea he has introduced details of the species of plants and animals involved ("On the Nature of Production in the Sea". Fish Invest., Lond., Ser. II, Vol. 22, No. 6. Pp. iii+40. London: H.M. Stationery Office, 1959. 10*s.* net). In place of the abstract idea of quantities of animal carbon eating quantities of plant carbon, he has developed an 'encounter' theory of grazing relating the speed of movement of copepods and the density of plant cells. This gives grazing-rates which are realistic in terms of the experimentally determined food requirements of the animals and the rates of depletion of plants in natural environments. His other innovation is to compute the growth of the *Calanus* populations, which are the dominant herbivores in the area studied, in terms of: (1) relations between plant density and egg laying; (2) the times taken to pass through the naupliar and copepodite stages; (3) probable mortalities at the various stages. His theoretical model of the production during the spring outburst of phytoplankton then gives results in terms of the numbers of *Calanus* (and similarly other copepods) that will be present at different times. The usefulness of this analysis has been shown in Dr. Cushing's previous work, where his results suggested that the aggregation of herring shoals on *Calanus* patches and their subsequent disengagement depended on a threshold concentration of *Calanus* in the patches ("Production and a Pelagic Fishery." Fish. Invest., Lond. Ser. II, Vol. 18, No. 7. Pp. 112. London: H.M. Stationery Office, 1955. 12*s*. 6*d*. net).

These detailed advantages, however, have certain drawbacks. Analyses in terms of particular species do not permit the easy comparison with other areas which is an important feature of the more abstract methods. For example, by conversion from plant cell-volume, Dr. Cushing gets a value for basic production during the spring. This value is only about one-quarter of those usually calculated for comparable areas, but it is difficult to see reasons for this divergence.

Another disadvantage of Dr. Cushing's model is that the possible effects on the plants of low nutrient concentrations are not included. Theoretically, this factor is used to make the more 'conventional' models stable; practically, it allows them to deal not only with the spring outburst when nutrients are comparatively plentiful, but also with summer conditions when they are scarce. Dr. Cushing points out, however, that although nutrient supply finally determines the quantity of production, this supply may depend not merely on the rate of uptake by the plants but also on the rate of return of inorganic nutrients to the water through herbivore excretion—a factor about which we know far too little. This could be particularly important in tropical oceanic areas where nutrients are at very low concentrations and where the high water temperatures may accelerate the biological re-cycling. Dr. Cushing's suggestion that production in these areas may be higher than formerly supposed is borne out by recent evidence, given at the International Oceanographic Congress in New York in September by Menzel and Ryther, that a significant outburst of production can occur in the northern Sargasso when nutrients are extremely low. Thus, production may depend on a balance between the physical and biological rates at which nutrients are made available to the plants. In the richer temperate and arctic areas, production may be mainly controlled by the supply of nutrients from the deeper waters, but it is possible that in tropical areas the rate of production is largely independent of such features of the physical environment and depends on how fast the plant-herbivore communities can re-cycle their nutrients.

Dr. Cushing, by his individual approach to these questions, has shown up some of the failings of the abstract methods, and particularly the need to make use of information about species composition and behaviour.

J. H. STEELE

IMMUNITY OF MICE SURVIVING SYSTEMIC LEUKÆMIA (*L*1210) TO ANTIFOLIC RESISTANT VARIANTS OF THE DISEASE

By DR. ABRAHAM GOLDIN, STEWART R. HUMPHREYS, GERALD O. CHAPMAN, DR. MICHAEL A. CHIRIGOS and JOHN M. VENDITTI

Laboratory of Chemical Pharmacology, National Cancer Institute, National Institutes of Health,
Public Health Service, U.S. Department of Health, Education and Welfare,
Bethesda 14, Md.

TWO of the halogenated derivatives of amethopterin, 3′5′-dichloroamethopterin and 3′-bromo-5′-chloroamethopterin, have been demonstrated to be markedly effective in the treatment of the transplantable acute lymphoid leukæmia *L*1210 in mice[1-4]. Employing these derivatives of amethopterin, it was possible to obtain extensive survival time and an appreciable number of survivors of systemic leukæmia *L*1210, even when treatment was initiated only several days prior to anticipated day of death.

With a relatively high level of inoculum (about 1,000,000 cells/mouse) injected subcutaneously, the *CDBA* mice employed in the above studies $(BALB/c\ An \times DBA/2J)F_1$ male mice succumbed characteristically in 10–12 days with systemic leukæmia, and a local tumour at the site of leukæmic inoculation (10–12 mm. in diameter). On treatment of advanced leukæmia with the dihalogenated derivatives of amethopterin, the local tumour at the site of leukæmic inoculation usually regressed after several treatments, and survival times of 90 days and beyond were not uncommon[4].

The mice that survived systemic leukæmia following treatment with the halogenated derivatives of amethopterin showed immunity on reinoculation of the leukæmia[4,5]. Many of the mice appeared to be highly refractory, and the leukæmic re-inoculum showed no evidence of growth. Other mice showed partial immunity. In the latter case, the re-inoculum grew slowly, but progressively, and the animals

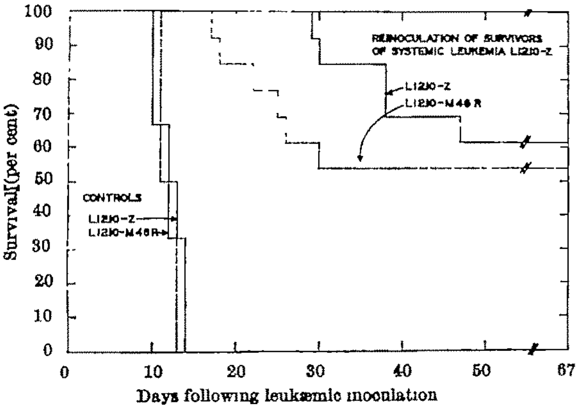

Fig. 1. Inoculation of the sensitive leukæmia (*L*1210*Z*) and an amethopterin-resistant subline (*L*1210–*M*46*R*) into *CDBA* mice surviving systemic leukæmia *L*1210 following treatment with 3′5′-dichloroamethopterin and 3′-bromo-5′-chloroamethopterin. Following treatment of leukæmic (*L*1210*Z*) mice with 3′5′-dichloroamethopterin and with 3′-bromo-5′-chloroamethopterin from day 7–90 there were 45/290 survivors on day 160. The mice were re-inoculated with *L*1210*Z* at that time, and there were 26/45 survivors on day 218 (ref. 5). These 26 mice were employed in the current study. Re-inoculated animals, 13 per group; controls, 6 mice per group, including the animals given the experimental and 1/10 of the experimental inoculum. Day 0 equals day 218 following the initial inoculation of leukæmia *L*1210. *L*1210*Z* Gen. 242; *L*1210–*M*46*R* Gen. 56. Approximately 500,000 cells per mouse, subcutaneously

eventually died, showing a rather extensive increase in survival time as compared with controls.

Similarly, the immune response to leukæmia *L*1210 has been elicited in 'out of strain' mice without the need for therapy[5]. When leukæmia *L*1210 was introduced subcutaneously into *BALB*/*c An* mice it grew at the site of inoculation. In some instances the growth was progressive, resulting in the death of the *BALB*/*c An* mice. In most instances the tumour regressed following the initial growth, and the mice were immune to re-inoculation of the disease.

The current study was undertaken to determine whether *CDBA* mice, apparently cured and immune to leukæmia *L*1210 as the result of therapy with the halogenated derivatives of amethopterin, or *BALB*/*c* mice, made immune to leukæmia *L*1210 following spontaneous regression of the tumour, would also be immune to antifolic resistant variant sub-lines of leukæmia *L*1210. For this study two antifolic resistant variants were employed: (*a*) An amethopterin-resistant variant of leukæmia *L*1210 (*L*1210–*M*46*R*). This variant of leukæmia *L*1210 appeared in response to therapy with amethopterin over several tumour generations[6]. *L*1210–*M*46*R* is resistant to therapy with amethopterin and shows a high degree of cross-resistance to the halogenated derivatives of amethopterin[6]. (*b*) The variant *L*1210–*M*66–3*R* was developed by therapy with 3′5′-dichloroamethopterin in serial transfer of leukæmia *L*1210. It has been demonstrated to be resistant to treatment with 3′5′-dichloroamethopterin over a wide range of doses[7].

The results of re-inoculation of drug-treated *CDBA* survivors of systemic leukæmia (*L*1210) with leukæmia *L*1210 and the resistant variant *L*1210–*M*46*R* are shown in Fig. 1. Treatment with 3′5′-dichloroamethopterin and 3′-bromo-5′-chloroamethopterin had been administered daily from the 7–90 day following leukæmic inoculation and the second inoculation with leukæmia *L*1210*Z* of the survivors had been on day 160[4,5]. The third inoculation (Fig. 1) employing *L*1210*Z* and *L*1210–*M*46*R* was on day 218. Fig. 1 shows that the mice with systemic leukæmia *L*1210, rendered immune by extensive treatment with the halogenated derivatives 3′5′-dichloroamethopterin and 3′-bromo-5′-chloroamethopterin, were immune, not only to the inoculation of the *L*1210 sensitive tumour, but were also immune to the *M*46*R* resistant variant of leukæmia *L*1210.

With both the *L*1210*Z* and the amethopterin-resistant variant *M*46*R* there were a considerable number of animals alive at 67 days following inoculation (285 days since the first inoculation of the leukæmic cells) (Fig. 1). At 67 days there were 8 out of 13 mice alive that had been re-inoculated with the sensitive tumour and 7 out of 13 mice alive that had received the amethopterin-resistant *M*46*R* tumour. The animals that did die following re-inoculation with *L*1210 or the *M*46*R* variant showed a marked increase in survival-time as compared with the controls inoculated for the first time. In general, as had been observed earlier for leukæmia *L*1210 in immune mice[4], they succumbed with large local tumours at the site of inoculation. The control mice for both the sensitive and resistant sub-lines had median survival times of 12 days. (The control mice employed in this experiment were somewhat younger than the immune mice. However, as indicated earlier[4], the immune phenomenon could not be attributed to an age factor. In more recent studies, this has been re-checked for both leukæmia *L*1210*Z* and the *L*1210–*M*46*R* variant.) For both the sensitive and resistant sub-line of leukæmia *L*1210 the inoculum-level employed was well above that required to give 100 per cent takes in control mice inoculated with tumour for the first time. With the *L*1210*Z* the experimental inoculum was 10 times greater than that giving 100 per cent takes in controls, while with the *L*1210–*M*46*R* it was 100-fold greater than that required to give 100 per cent takes in controls.

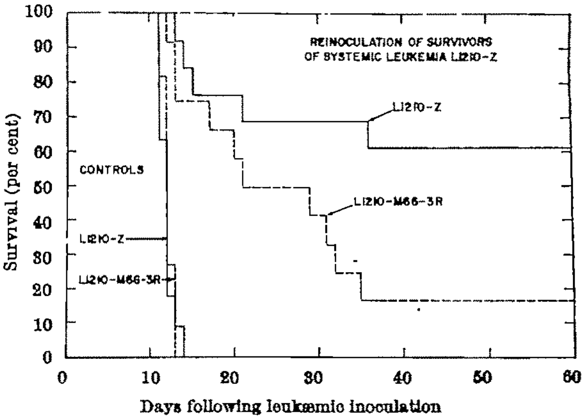

Fig. 2. Inoculation of the sensitive leukæmia (*L*1210*Z*) and a 3′5′-dichloroamethopterin-resistant subline (*L*1210–*M*66–3*R*) into *CDBA* mice. The re-inoculated mice had survived systemic leukæmia following treatment with 3′5′-dichloroamethopterin. Thirteen mice were re-inoculated with leukæmia *L*1210*Z* and 12 mice were re-inoculated with *L*1210–*M*66–3*R*. These mice were survivors of several experiments. All had been treated with 75 mgm./kgm. 3′5′-dichloroamethopterin starting at 7 days following leukæmic inoculation, and with one exception treatment was to the 50–80th day. Three of the mice re-inoculated with *L*1210 and four of the mice inoculated with *L*1210–*M*66–3*R* had already been shown to be immune to *L*1210. The remainder of the long-term survivors were re-inoculated for the first time. Controls, 11 mice/group of age comparable to that employed in the experiments. *L*1210*Z* and *M*66–3*R* inocula approximately 500,000 cells per mouse, subcutaneously. The inoculum concentration for both tumours was 100 times greater than that required to give 100 per cent takes in controls. *L*1210*Z* generation No. 267. *L*1210–*M*66–3*R* generation No. 20

Table 1. INOCULATION OF LEUKÆMIA *L*1210*Z* AND AN AMETHOPTERIN RESISTANT SUBLINE (*L*1210–*M*46*R*) INTO *BALB/c An* MICE IMMUNIZED AGAINST THE SENSITIVE LINE (*L*1210*Z*)

Approximately 25 mgm. spleen inoculated per mouse (see ref. 5).

Fig. 2 summarizes results obtained when the variant *L*1210–*M*66–3*R* was utilized in a similar experiment. *CDBA* survivors of systemic leukæmia *L*1210*Z* exhibited immunity not only to subsequent inoculation of *L*1012*Z*, but also to the variant *L*1210–*M*66–3*R* resistant to 3′5′-dichloroamethopterin. Without any further therapy immune mice re-inoculated with each of these tumours showed extensive survival-time as compared with controls inoculated with either tumour for the first time.

It is of interest to note that the immune response appeared to be more extensive in mice re-inoculated with *L*1210*Z* as compared with *L*1210–*M*66–3*R*. There were 8 out of 13 sixty-day survivors on re-inoculation with *L*1210*Z* and 2 out of 12 sixty-day survivors following inoculation with *L*1210–*M*66–3*R*. By the same token the immunity to rechallenge with *L*1210*Z* appeared to be somewhat more extensive than to challenge with the *L*1210–*M*46*R* (Fig. 1). The nature of these differences is under further investigation.

Similarly, mice of strain *BALB/c An* immunized against leukæmia *L*1210, without drug therapy, were also immune to subsequent inoculation of the resistant variants *L*1210–*M*46*R* and *L*1210–*M*66–3*R*. This is illustrated for the *M*46*R* variant in Table 1. Group 1 had received the sensitive *L*1210*Z* as the first implant[5]. In 4 out of 10 mice the tumour grew progressively and the animals succumbed. In the remaining 6 mice the tumour regressed and the animals survived. On the second inoculation with leukæmia *L*1210 the tumour failed to grow. The third inoculation was with *M*46*R* and the tumour did not take.

In group 2 (Table 1) the *L*1210*Z* had been inoculated once into the *BALB/c An* mice. The tumour grew locally and then regressed in all but one mouse. The nine survivors were inoculated with the *L*1210–*M*46*R* resistant variant and showed no evidence of tumour growth. In contrast, *BALB/c An* mice receiving the *M*46*R* variant for the first time (group 3) developed large local tumours at the site of inoculation, averaging 12 mm. in diameter. Four out of 10 mice succumbed to progressive tumour growth. In the remaining 6 animals the tumour regressed.

It is noteworthy that the *CDBA* mice and leukæmia *L*1210 appear to be highly compatible. The immune response has not been observed in non-treated leukæmic *CDBA* mice. In this hybrid the leukæmia has never been observed to undergo spontaneous regression, and survivors of inoculum-levels too low to produce leukæmia have invariably been susceptible to re-inoculation.

In all the above experiments the source of inoculum was a suspension of leukæmic spleen taken from *DBA*/2 mice, the strain of origin[8]. It is of interest to point out that attempts to immunize *CDBA* mice against *L*1210*Z* by pre-inoculation of *DBA*/2 spleen from normal mice have been unsuccessful[6]. The immune response in *CDBA* mice has been observed only following successful therapy of leukæmia with the halogenated derivatives. Results were obtained suggesting that the immune response is not readily demonstrable unless successful therapy is initiated after the disease has become systemic[5].

On the other hand, transplantation of *DBA* spleen from normal mice into out-of-strain mice has been demonstrated to immunize mice against subsequent inoculation of *L*1210 or the antifolic variants[7].

Since the leukæmic mice treated successfully with the dihalogenated derivatives of amethopterin developed immunity to the disease, it has been suggested that this immunity may contribute to the success of the drugs in chemotherapy[4]. Conceivably, chemotherapy may so alter or influence tumour cells that homograft characteristics are acquired or unmasked, thereby facilitating further therapy[5,9]. This would raise the question as to whether the origin of resistance to antifolic therapy is attributable to resistance to the drug *per se*, or to resistance to a therapeutically induced immune mechanism.

The current studies provide a separation between tumour cell resistance to therapy as opposed to tumour cell resistance to host immunity. The two variants of leukæmia *L*1210, *M*46*R*, and *M*66–3*R*, are resistant to antifolic therapy but are inhibited by the induced immunity of the host. Thus, although the immune mechanism may contribute to therapy, resistance to therapy does not necessarily imply abrogation of the effectiveness of the immune response. Interrelationships of chemotherapeutic and immunological phenomena in host-tumour systems are under further study. Elucidation of such phenomena may contribute to our knowledge of both transplantation and chemotherapy.

We wish to thank Gerome McDowell for capable technical assistance.

REDUCTION OF INTESTINAL ABSORPTION BY A SYNTHETIC CHEMICAL

By DR. J. A. NISSIM

Pharmacology Department, Guy's Hospital Medical School, London, S.E.1

A SYNTHETIC bactericidal substance, trimethylhexadecylammonium stearate, was submitted to a study of pharmacological properties prior to a proposed trial in certain human alimentary infections. Preliminary studies showed loss of weight, which was first believed to be due to reduced food intake. Daily measurement of the food residue of control and treated groups showed no reduction in the food consumption of the latter, however, until a very late stage when the animals became moribund.

The animals used in these experiments were mainly adult male mice from non-interbred *O* stock. The water-insoluble trimethylhexadecylammonium stearate was incorporated in diet 41 (powder form), 5 gm. of which was given to each mouse per day. The concentration of the drug and the loss in weight after one month, or in the case of the three higher doses, at the time of death, are shown in Table 1. Analysis of variance gave $P \leqslant 0 \cdot 001$ for linear regression and for the variance between doses. Deviation from regression was not significant.

The histological appearances in mice receiving 0·4 and 0·5 per cent of the drug were compatible with the varying degrees of damage found in starved mice. In addition, most of the animals in these two groups showed at the time of death coffee-ground hæmorrhages in a specific area extending from the pyloric portion of the stomach to the ileum. This was invariably associated with damage to the intestinal villi, which involved primarily the epithelial lining. No hæmorrhages were noted in groups receiving smaller concentrations of the drug, though the animals still showed the appearances typical of inanition with total absence of depot fat and reduction in the weight of the testes and seminal vesicles ($P < 0 \cdot 001$). Animals receiving 0·1 per cent trimethylhexadecylammonium stearate died after 2–4 months of treatment, but some survived longer. The fæces were well formed in all groups, and the loss of weight could not, therefore, be attributed to intestinal hurry due to irritation. A few of the animals given 0·05 per cent of the drug for three months or more showed marked hypertrophy and hyperplasia of the duodenum and jejunum (Figs. 1 and 2).

Adult mice receiving 0·02 per cent trimethylhexadecylammonium stearate for six months did not differ from control mice either in weight or in general appearance. The rate of growth of immature mice given this concentration of the drug for periods of a fortnight at a time, in alternation with equal periods on diet 41, was depressed. The average fortnightly gain in weight per mouse was 2·5 gm. on the drug, as compared with 3·4 gm. for the control group ($P < 0 \cdot 001$).

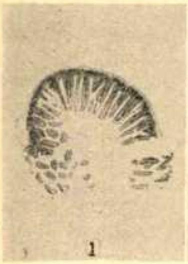

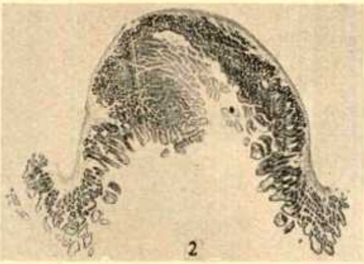

Fig. 1. Control: jejunum of normal mouse

Fig. 2. Jejunum of mouse kept on 0·05 per cent trimethylhexadecylammonium stearate in diet 41 for 3 months

A suspension of trimethylhexadecylammonium stearate in 0·5 per cent 'Tween 80' was administered to mice by stomach tube in doses of 25, 10, 5 and 2·5 mgm. daily. Given in this manner, the drug proved 3–5 times more effective than in diet 41. The animals died within 3, 7 and 9 days, and showed similar loss of weight and histopathological findings after the first three doses. Reduction of appetite became evident only in the terminal stages. With the latter dose, there was loss of weight comparable with that obtained on 0·1 per cent in the diet. The mice receiving this dose were alive and well after 10 weeks of treatment, though slimmer than a control group receiving 'Tween 80' only by the same route.

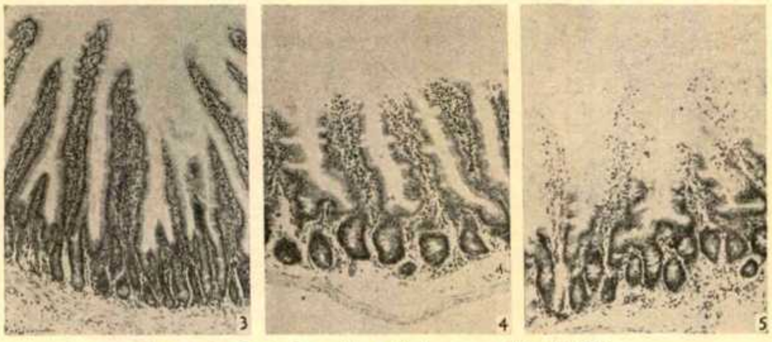
Trimethylhexadecylammonium stearate was more toxic when given subcutaneously in the form of the 'Tween' suspension. The *LD*50 was of the order of 0·6 gm./kgm. body-weight, a dose smaller than that received in a single day in a diet containing 0·5 per cent of the drug. After a dose of 1·0 gm./kgm., all the mice died within 24 hr., and 18/20 of these animals showed the characteristic intestinal hæmorrhages due to damage of the mucosa and villi in the pyloric area, duodenum and jejunum (Figs. 3–8). Single doses of 0·25 gm./kgm. did not cause death, but the animals continued to lose weight for some 10 days, and the difference in weight from a control group at one week was highly significant ($P < 0{\cdot}001$).

Administration via the intraperitoneal route proved more toxic still. The *LD*50 was of the order of 0·05 gm./kgm. for C_3H mice and 0·08 gm./kgm. for ordinary stock mice. Post-mortem usually showed marked dilatation of the stomach and intestine in addition to the previously described findings. Doses of 0·025–0·05 gm./kgm. given weekly for 10 weeks to eight mice on unrestricted diet resulted in gain of weight of 0·5 gm. as compared with 2·5 gm. per mouse in the control group.

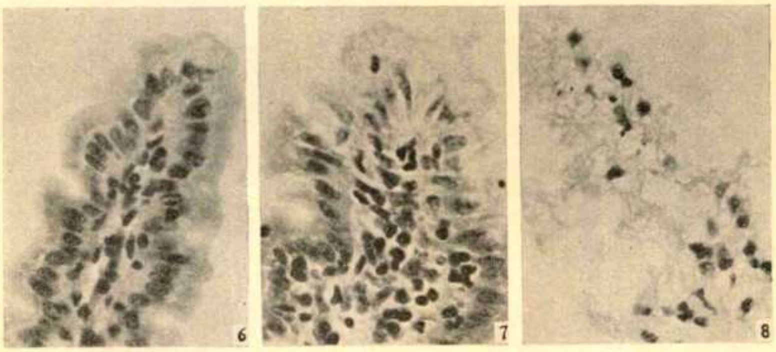
Animals allowed to recover after losing a fifth to a quarter of their body-weight (average loss = 4 gm.), either by continued administration of the drug in the diet (12 mice) or by a single subcutaneous administration (12 mice), were restored to normal weight when put on unrestricted normal diet. There was no obvious injurious effect on health up to three months after the end of the experiment, and the animals were indistinguishable from those in the control group.

The above results suggest that trimethylhexadecylammonium stearate has a specific effect on the mucosal cells of the villi in the pyloric, duodenal and jejunal regions of the gastro-intestinal tract, since the effect is obtained no matter what route is employed for administration of the drug. Large doses of this substance bring about the total destruction of mucosal epithelial cells and lead to the degeneration and collapse of the whole villus, whereas smaller doses appear to reduce the functional efficiency of the mucosal cell probably both in its absorbing as well as its digestive roles. The hypertrophy and hyperplasia following continued oral administration of 0·05 per cent of trimethylhexadecylammonium stearate in the diet seem to represent an effort on the part of the intestine to overcome the functional difficulty imposed by the drug. It would seem akin to the compensatory hypertrophy of a strained myocardium. The thickening is absent in the ileum and colon. This hypertrophy has also been noted occasionally after repeated intraperitoneal injection of the drug. (Intestinal hypertrophy was not produced by new batches of trimethylhexadecylammonium stearate, so that the exact composition of the batch and percentage of impurities may play an important part.)

A substance with such specific pharmacological activity opens up two important research fields. As a research tool it should prove a great aid in the study of intestinal absorption and the many enzymes



Figs. 3–5. Control, medium effect, severe effect (×60)



Figs. 6–8. Control, medium effect, severe effect (×420)

Figs. 4 5, 7 and 8. Jejunums of mice showing moderate and severe damage to villi after subcutaneous injection of trimethy lhexadecylammonium stearate (1·0 gm./kgm.

that are probably concerned in this function. Furthermore, drugs which reduce food absorption may prove valuable in the control of obesity, atherosclerosis and coronary thrombosis.

Finally, the drug was tried on a healthy adult male volunteer. Three consecutive courses of the drug were administered at monthly intervals for periods of three, two and two weeks, respectively, and have resulted in loss of weight of 15, 9 and 7 lb., respectively. The drug was taken in the form of capsules in divided doses, and the average daily doses in the three courses were 1·0, 0·75 and 0·7 gm. This moderate dosage resulted in increase in the bulk and softness of the fæces, whereas a daily dose of 1·5 gm. was associated with mild nausea and fluid stools, but no colic or tenesmus. The effects of the drug were again evidently reversible, since, with over-eating, 7 and 4 lb. weight were put on rapidly at the end of the first and second courses. The total loss in weight was 20 lb.

α,ε-DIAMINOPIMELIC ACID: ITS DISTRIBUTION, SYNTHESIS AND METABOLISM

By Dr. L. E. RHULAND

Research Laboratories, The Upjohn Co., Kalamazoo, Mich.

THE introduction of paper partition chromatography by Consden *et al.*[1] made it possible to identify the components of many complex organic substances, and introduction of this technique stimulated numerous studies designed to characterize the amino-acid content of many natural products. One such study, first reported by Elizabeth Work[2], indicated the presence of a new ninhydrin positive material, designated as spot No. 17, in hydrolysates of both insoluble cell residues and, although in much lower concentration, in ethanol extracts of *Corynebacterium diphtheriae*. At about the same time an amino-acid with similar chromatographic behaviour was found in hydrolysates of soil[3], rumen contents of sheep (see footnote in Work[4]) and in a lipopolysaccharide fraction from *Mycobacterium tuberculosis*[5]. It remained for Dr. Work, however, in an excellent piece of work, to isolate, characterize and identify this new amino-acid as α,ε-diaminopimelic acid[6].

Properties and Distribution

Properties. Diaminopimelic acid is a neutral compound, moderately soluble in cold water and aqueous alcohol. It is soluble in dilute acid or alkali and is insoluble in ethanol and all organic solvents[4,6].

α,ε-Diaminopimelic acid can be synthesized chemically by the method of Sørenson and Anderson[7] or Sheehan and Bolhofer[8], yielding, in either case, three isomers, the DD, LL and *meso*. Separation of the three isomeric components has been achieved[9] by preparing the diaminopimelic acid diamide dihydrochloride, removing the *meso* diamide by fractional crystallization and resolving the DL racemate with hog kidney amidase[10]. The enzyme-treated racemate was then fractionated on the cation-exchange resin, 'Amberlite *XE*-64', and the respective isomers crystallized. The original procedure of Work *et al.*[9] has been modified by Wade *et al.*[11], who prepared the dicarbobenzoxy derivative which permits separation of the soluble dicarbobenzoxy-*meso*-diaminopimelic acid from the insoluble dicarbobenzoxy-DL-diaminopimelic acid. The diamide was prepared from the above compound, the carbobenzoxy groups removed by hydrogenation and the DL-diaminopimelic acid diamide resolved as described by Work *et al.*[9]. The dissociation constants of *meso* and LL-α,ε-diaminopimelic acid were identical: pk'_1 1·8, pk'_2 2·2, pk'_3 8·8, pk'_4 9·9, but differences in the infra-red spectrum of the two compounds in the region of 6–8μ were observed[11].

The distribution of the various stereoisomers of α-ε-diaminopimelic acid has been studied[12–14], and it is clear that all three isomers are found in micro-organisms. The *meso* isomer or combinations of the *meso* and L-isomers seemed to be the most prevalent form of α,ε-diaminopimelic acid, although some of the *Propionibacteria*, *Streptomyces* and *Clostridia* contain only the L-isomer. The Micromonospora appear to contain all three isomers.

Distribution. Work[6] concluded that α,ε-diaminopimelic acid was probably restricted to protein of bacterial origin, since it had not been reported in the literature concerned with the chromatography of mammalian cell protein hydrolysates or tissue fluids. To check this hypothesis, Work and Dewey[15] conducted a survey of 118 micro-organisms, etc., including fungi, algae, protozoa and viruses, which revealed that α,ε-diaminopimelic acid was present in all the bacteria examined with the exception of the Gram-positive cocci. It was also found in two species of Myxobacteriales and in three species of Myxophyceae. It was absent, however, from yeast, fungi, two strains of protozoa, tobacco mosaic and turnip yellow mosaic virus. Knight[16], in a survey of the amino-acid composition of tomato bushy stunt, influenza *A* and *B*, Shope papilloma, cucumber virus and T_3 bacteriophage did not report the presence of α,ε-diaminopimelic acid in these viruses.

In the original survey[15], α,ε-diaminopimelic acid was reported to be absent from actinomyces and streptomyces but that these organisms contained instead another new amino-acid. This substance was designated as compound *A*. Work[17,18] presented evidence suggesting that compound *A* was a methyl homologue of α,ε-diaminopimelic acid, but subsequent studies[14], using the chromatography system of Rhuland *et al.*[19], revealed that compound *A* was LL-diaminopimelic acid. Cummins and Harris[20,21] and Cummins[22] reported that when α,ε-diaminopimelic acid was found in whole-cell hydrolysates, it was always present in the cell wall.

α,ε-Diaminopimelic acid has been found in soil hydrolysates[3], in caseous tuberculous nodules and caplan nodules[23], in pine tree pollen[24] and in alcohol extracts of neoplastic tissues[25]; but in all cases except the latter the presence of bacterial contamination could not be eliminated. Seibert *et al.*[25], using an α,ε-diaminopimelic acid auxotroph, obtained growth of that organism in the absence of α,ε-diaminopimelic acid when drops of tissue hydrolysates were added to the bioautographic plates. These results must be re-examined with great care, however, since lanthionine was also present in the tissues, and this compound in the presence of trace amounts of α,ε-diaminopimelic acid, for example, when using an unwashed inoculum of *E. coli* 173–25, will support the growth of *E. coli* 173–25 (ref. 26). Seibert *et al.*[25] reported that lanthionine will support the growth of the *E. coli* auxotroph, but this was not confirmed by Rhuland[26] or Meadow *et al.*[27], using the same test organism.

With the finding of Salton[28] that α,ε-diaminopimelic acid exists in the cell walls of *E. coli*, *Salmonella pullorum* and *B. subtilis*, numerous reports have appeared revealing the presence of this amino-acid in various cell fragments. Smith *et al.*[29] found α,ε-diaminopimelic acid in the peptide fraction of a cell wall polysaccharide from *B. anthracis*, and its presence in a soluble peptide, produced by germinating spores of *B. megaterium*, was shown by Strange and Powell[30]. The recent review by Strange[31] should be consulted for a more detailed account of the occurrence of α,ε-diaminopimelic acid in various cell wall peptides of the bacilli. Koch and Dreyer[32] demonstrated the same amino-acid in fragments released by bacteriophage, as have Weidel and Primosigh[33]. A recent publication by Strominger[34] indicated that *meso*-α,ε-diaminopimelic acid occurs in a 'Park's type nucleotide' (Park[35]) in *E. coli*.

With the exception of the demonstration of α,ε-diaminopimelic acid in *Corella ellipsoidia* by Fujiwara and Akabori[36], it appears that the distribution of this amino-acid is limited to the Schizomycetes and the Myxophophyceae, thus lending support to the thesis of Stanier and VanNiel[37] that these groups should be combined into one kingdom, the Monera.

Isolation. The lysine auxotroph, *E. coli* 26–26, isolated by Davis[38], accumulates large amounts of α,ε-diaminopimelic acid in the culture medium and can be used as a source of *meso* and LL-α,ε-diaminopimelic acid. Wright and Cresson[39] used an ion-exchange chromatography procedure involving adsorption of the amino-acid on 'Dowex-1' (OH$^-$) followed by elution with 0·2 *N* hydrochloric acid, removal of anions in the α,ε-diaminopimelic acid fractions with 'Dowex-1' (HCO$_3^-$) and finally deionization with *IR*-4*B* (OH$^-$) and *IRC*-50 (H$^+$). Crystallization of α,ε-diaminopimelic acid was achieved by adding ethanol to concentrated solutions of α,ε-diaminopimelic acid after final de-ionization.

Work and Denman[40] used a somewhat simpler procedure employing acid-washed 'Zeokarb-225'. Contaminating amino-acids, aspartate, glutamate, glycine, alanine and valine were removed first with 1·5 *N* hydrochloric acid. Some 2·5 *N* hydrochloric acid was then added to elute the α,ε-diaminopimelic acid. The amino-acid hydrochloride was crystallized directly from the concentrate or obtained as the free base after removal of chloride ion with deacidite. I have used this same procedure, except that 'Dowex-50' (200–400 mesh) was used as the resin, to obtain α,ε-diaminopimelic acid labelled with carbon-14 from culture filtrates of *E. coli* 26–26 grown on uniformly labelled glucose. Ikawa and O'Barr[41] used the 'Dowex-50' procedure to obtain *meso*-diaminopimelic acid from acid hydrolysates of *Lactobacillus arabinosus*.

Since *E. coli* produces *meso* and LL-α,ε-diaminopimelic acid, both isomers are obtained by these resin procedures, although, as shown by Wright and Cresson[39], the LL isomer may be removed by recrystallization. Hoare and Work[18] attempted to separate the two isomers by the procedure of Work and Denman[40], but were unable to achieve a practical method of separation.

Figueroa and Seibert[42] studied the chromatography of α,ε-diaminopimelic acid on starch columns, and found that this procedure does not separate α,ε-diaminopimelic acid from lysine.

E. coli 26–26 and high-producing mutants derived from it have been used in the commercial production of lysine[43]. In this patented process toluene-treated cells of *A. aerogenes* are added to fermentation broths containing large quantities of α,ε-diaminopimelic acid; the lysine, obtained after decarboxylation of the α,ε-diaminopimelic acid, is isolated by resin chromatography.

Metabolism

Oxidation. Natural diaminopimelic acid from *Corynebacterium diphtheriae*, the *meso* isomer, was shown by Burton[44] to be oxidized by the L-amino-acid oxidase of *Neurospora crassa* with the consumption of one atom of oxygen and the liberation of one molecule of ammonia per molecule of amino-acid (see also Work[6]). Bonetti (personal communication to Work[6]) reported that this same preparation was not oxidized by kidney D-amino-acid oxidase or ophio L-amino-acid oxidase. Subsequent studies by Work[45] revealed that the *Neurospora* oxidase attacks *meso*, LL-α,ε-diaminopimelic acid and the L-diaminopimelic acid-D-monoamide at about the same rate. The L-amino-acid oxidases of viper and rattlesnake attacks the *meso* and L-isomers at a much slower rate than the *Neurospora* oxidase, but metabolized the L-diaminopimelic acid-D-monoamide at a rate almost comparable with the *Neurospora* preparation. The DD-isomer was not attacked nor did it have any effect on the course of oxidation of the other isomers.

Racemization. A racemase, present in acetone-dried cells of *E. coli* 26–26 (lysine auxotroph), converts L-diaminopimelic acid to the *meso* isomer[46]. Subsequent studies[47,48] have revealed some of the properties as well as the distribution of this enzyme. Diaminopimelic acid racemase acts on either *meso* or L-diaminopimelic acid, but has no activity on the DD-isomer. As Antia *et al.*[48] pointed out, the substrate for this enzyme is unusual in that it has two asymmetric carbon atoms which are symmetrical about the γ-carbon atom. The experimental evidence presented indicates that one end of the α,ε-diaminopimelic acid molecule must be in the L-configuration to ensure enzymatic activity.

Diaminopimelic acid racemase was found in almost all bacteria containing α,ε-diaminopimelic acid, although there was no correlation between the type of isomer and racemase content[48]. It is noticeably absent from certain *Clostridia*, but present in several of the Micrococci which do not contain α,ε-diaminopimelic acid.

Decarboxylation. The structural relationship of α,ε-diaminopimelic acid and lysine and the established presence of amino-acid decarboxylases in bacteria[49] suggested an important metabolic relationship between these two amino-acids involving a possible mechanism of lysine biosynthesis in bacteria.

Dewey and Work[50] demonstrated that α,ε-diaminopimelic acid was indeed decarboxylated to lysine by some strains of *E. coli*. The enzyme, as most decarboxylases, was most active in cells grown at acid *p*H, but unlike the previously reported cases, was constitutive rather than adaptive. Davis[38] implicated α,ε-diaminopimelic acid as a precursor of lysine with his finding that a number of lysine auxotrophs accumulated large amounts of α,ε-diaminopimelic acid in the culture supernatant. Vogel[51], studying the metabolism of [4-^{14}C] aspartate in strains of *Hydrogenomonas facilis*, *Pseudomonas fluorescens*, *Azotobacter agilis*, *Agrobacterium radiobacter*, *Alcaligenes faecalis*, *Escherichia coli*, *Micrococcus lysodeikticus*, *Arthrobacter globiformis*, *Bacillus subtilis* and *Streptomyces griseus*, found what appear to be a single over-all mode of lysine biosynthesis, presumably via α,ε-diaminopimelic acid. Similar studies with *Chorella vulgaris* and *Euglena gracilis*[52] revealed that the *Chorella* containing α,ε-diaminopimelic acid synthesize lysine via the α,ε-diaminopimelic acid pathway, while the *Euglena* not containing α,ε-diaminopimelic acid utilized the fungi pathway of lysine biosynthesis, thus lending support to the thesis advanced by Dewey and Work[50] and Davis[38]. Recent experiments by Meadow and Work[53], using an auxotroph of *E. coli* that requires only α,ε-diaminopimelic acid for growth, report that, in this organism, lysine can be synthesized by a metabolic sequence that does not proceed via α,ε-diaminopimelic acid. This conclusion is based on the finding that this auxotroph, *E. coli* 173-25-*D*, grown on glucose labelled with carbon-14, incorporated radioactivity in the cellular lysine, but not the α,ε-diaminopimelic acid.

With the implication of α,ε-diaminopimelic acid as an intermediate in the biosynthesis of lysine it was important not only to determine the distribution of this enzyme, but also to ascertain with certainty that the decarboxylation of α,ε-diaminopimelic acid was not due to a non-specific lysine decarboxylase. That a specific α,ε-diaminopimelic acid decarboxylase was present was clearly demonstrated by Dewey and Work[50] using the lysine auxotroph isolated by Davis[38] which contained lysine decarboxylase, but no α,ε-diaminopimelic acid decarboxylase. Additional proof was obtained by growing *E. coli* in a glucose salts medium which, under these conditions, contains no lysine decarboxylase but does contain the constitutive α,ε-diaminopimelic acid decarboxylase.

Dewey and Work[54] reported the presence of α,ε-diaminopimelic acid decarboxylase in *Aerobacter aerogenes* and, in a later paper, Dewey[55] surveyed a number of strains of the *coli-aerogenes* group and other bacteria for the presence of this enzyme. The results of the survey indicated that the enzyme is widely distributed in the *coli-aerogenes* group. The enzyme was also found in a strain of *Pseudomonas aeruginosa*, but not *Proteus vulgaris*, *Streptococcus faecalis* or *B. subtilis*. Work[56] and Dewey *et al.*[57], in further studies of this type, reported the presence of the enzyme in *Actinomyces* sp., *Rhodopseudomonas spheroides*, *Rhodospirillum rubrum* and in three organisms which do not contain α,ε-diaminopimelic acid, *Sarcina lutea*, *Staphylococcus aureus* and *Streptococcus faecalis*. Powell[58] has reported the enzyme to be present in spores of *B. sphaericus*, as has Willett[59] in *Mycobacterium tuberculosis*.

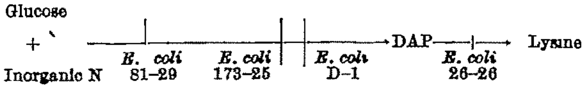
Diaminopimelic acid decarboxylase, unlike most amino-acid decarboxylases, is a constitutive rather than adaptive enzyme[60] and, although formed in cells grown at an acid *p*H, must be assayed at *p*H 6·8 for maximum activity[60]. The enzyme is specific for α,ε-diaminopimelic acid and will not decarboxylate a number of closely relative compounds such as diaminoadipic acid, diaminosuberic acid, α,ε-diamino-β-hydroxypimelic acid, lanthionine or pyridine-2,6-dicarboxylic acid[57,60].

Diaminopimelic acid decarboxylase can be partially purified by fractional extraction with acetone[60] and, although inhibitor studies have shown that it is a very sensitive sulphydryl enzyme, the co-factor requirements have not been ascertained. Pyridoxal phosphate is required for maximal activity[60], but an absolute requirement for this coenzyme has not been demonstrated. The α,ε-diaminopimelic acid and lysine decarboxylase levels in pyridoxin-deficient *E. coli* have been determined[61], but the results failed to show the expected absolute requirement for pyxidoxal phosphate. Similar results were obtained by Powell and Strange[62] with *B. sphaericus*. Meadow and Work[63] studied the α,ε-diaminopimelic acid decarboxylase from *B. sphaericus* in more detail, using a number of pyridoxine inhibitors, but again were unable to demonstrate the absolute requirement of pyridoxal phosphate in this reaction. These workers concluded that there was a low affinity between enzyme and pyridoxal phosphate in *B. sphaericus*.

Initial studies with α,ε-diaminopimelic acid decarboxylase revealed that the enzyme was relatively specific for *meso*-α,ε-diaminopimelic acid, but that acetone-dried cells of *A. aerogenes* decarboxylated LL-α,ε-diaminopimelic acid[18]. Activity against the L-isomer was not always obtained, and Hoare[44] resolved this difficulty with the finding that the apparent decarboxylation of LL-α,ε-diaminopimelic acid was due to its conversion to the *meso* isomer by racemase activity. The D-isomer was not metabolized by α,ε-diaminopimelic acid decarboxylase[46,48].

Transamination. With the widespread distribution of transaminases in bacteria, it is perhaps not unreasonable to expect that α,ε-diaminopimelic acid could act as an amino donor in such a reaction. Evidence demonstrating this reaction was reported by Meadow and Work[64] using acetone-dried cells of *E. coli*, *B. cereus*, *B. sphaericus*, *S. lutea*, *A. aerogenes* and *S. saprophyticus*. Contrary to the racemase, oxidase and decarboxylase reactions, the D-isomer was shown to participate in the transaminase reaction and in the *S. lutea* preparation was transaminated faster than the *meso* isomer. In general, pyruvate, oxalacetate and oxoglutarate act as amino acceptors, but the rate varies with the organism and with the stereoisomer used. Using *B. sphaericus*, Meadow and Work[64] reported that concentrations of pyridoxal phosphate from 1μ to 100μ moles progressively increased the rate of transamination.

Biosynthesis. It is perhaps pertinent to start a discussion of α,ε-diaminopimelic acid biosynthesis with a description of the bacterial mutants which have been used to elucidate in part the mechanism of α,ε-diaminopimelic acid biosynthesis. A number of these mutants have been reported by Davis[38] and enable one to write the following sequence:



E. coli 81–29 requires DAP or lysine if aspartic acid is present in medium.

E. coli 173–25 requires DAP.

E. coli D–1 accumulates *N*-succinyldiaminopimelic acid.

E. coli 26–26 requires lysine, accumulates DAP.

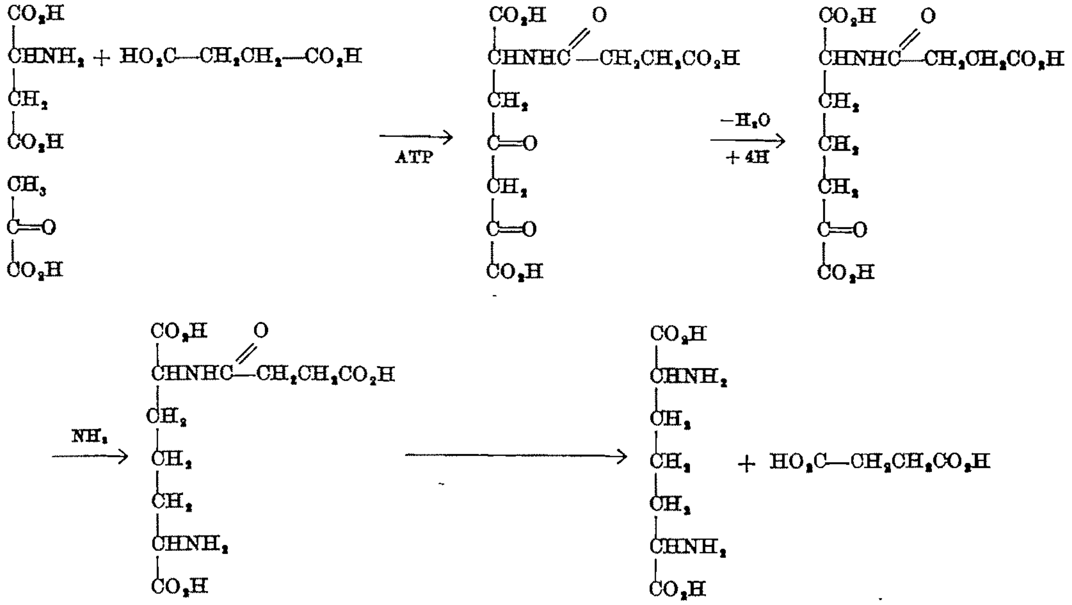
DAP, α,ε-diaminopimelic acid.

As a result of studies of amino-acid biosynthesis with various compounds containing carbon-14, Abelson *et al.*[65] were able to demonstrate that four of the carbon atoms of α,ε-diaminopimelic acid and lysine were derived from aspartic acid. In these studies aliquots of cell hydrolysates were subjected to paper chromatography and the specific activity of the radioactive amino-acids determined directly on the paper. Rhuland and Bannister[66], using *E. coli* 26-26 (accumulates α,ε-diaminopimelic acid) culture filtrates, isolated a compound capable of supporting the growth of *E. coli* 81-29 in the absence of α,ε-diaminopimelic acid. The compound was identified as succinic acid and, as shown by the same authors, was required for maximal synthesis of α,ε-diaminopimelic acid by cell-free preparations of *E. coli* 26-26. In addition to succinic acid, aspartate, pyruvate, adenosine triphosphate and triphosphopyridine nucleotide were also shown to be required in this synthesis. Similar results were reported by Gilvarg[67] with the exception that both di- and tri-phosphopyridine nucleotide were indicated as stimulating α,ε-diaminopimelic acid synthesis, and glutamate instead of succinate was listed as one of the components of the reaction. Subsequent studies by Gilvarg[68] reported the isolation of *N*-succinyl-L-diaminopimelic acid from *E. coli D*-1. This compound was enzymatically hydrolysed to succinic acid and α,ε-diaminopimelic acid by extracts of *E. coli* 26-26 and *E. coli W* (wild type), but not *E. coli D*-1, thus indicating its role as an intermediate in the synthesis of α,ε-diaminopimelic acid and offering an explanation for the function of succinic acid as a growth factor for an α,ε-diaminopimelic acid auxotroph[66]. Additional studies[69] have revealed that the succinyl side-chain is attached to the aspartate portion of N-succinyl-L-diaminopimelic acid.

Gilvarg[70], in a more detailed report of his original observation, confirmed the results of Abelson *et al.*[65], demonstrating that in cell-free extracts, as well as in growing cells, aspartate contributes four of the carbon atoms in the α,ε-diaminopimelic acid molecule. In this study, contrary to the previous report[67], triphosphopyridine nucleotide was indicated as the coenzyme of choice, thus confirming the results of Rhuland and Bannister[66] and Rhuland and Soda[71]. Although the original preliminary report of Gilvarg[67] did not point out which coenzyme was most effective, the coenzyme requirement may depend on the condition of the cells used for preparing α,ε-diaminopimelic acid synthesizing enzymes since Rhuland and Soda[71] showed that diphosphopyridine nucleotide is the preferred coenzyme in extracts from aged cells, but not in extracts from fresh cells. It does not seem likely, however, in view of the results of Rhuland and Soda[71] indicating that glutamate is no more active, with the exception of succinate, than the other Krebs cycle compounds in stimulating α,ε-diaminopimelic acid synthesis, that this compound is used *per se* in this synthesis. It would seem that this evidence and a consideration of the facts that acetyl or formyl aspartate are not used in the reaction[70] along with the isolation of N-succinyldiaminopimelic acid are adequate indications of the role of succinic acid in the reaction sequence under discussion.

The accumulation of 2,N-succinyl-6-ketopimelic acid, in addition to N-succinyldiaminopimelic acid, by *E. coli D*-1 is described by Gilvarg[72]. This compound can be transaminated to N-succinyl-L-diaminopimelic acid by extracts of *E. coli* using glutamic acid as the amino donor. Another brief report[73] described the purification of the transaminase and its specificity for glutamic acid as the amino donor. This transaminase has also been detected in *A. aerogenes*, *A. agile*, *M. lysodeikticus* and *R. spheroides*.

Rhuland and Soda[71] presented evidence revealing that an N-substituted-keto-pimelic acid was made by extracts capable of synthesizing α,ε-diaminopimelic acid. The compound was converted to α,ε-diaminopimelic acid after reductive hydrogenolysis of the 2,4-dinitrophenylhydrazone followed by acid hydrolysis. These results have enabled the above authors to write a tentative mechanism for α,ε-diaminopimelic acid biosynthesis which up to the present time appears to be compatible with the experimental results reported in the literature. The mechanism is as follows.



It is clear from a consideration of this mechanism that the synthesis of α,ε-diaminopimelic acid from small carbon fragments involves seven or eight enzymatic steps with the formation of some new and novel organic compounds. However, it is interesting to note that the enzymatic studies reported thus far have not indicated co-factor requirements other than triphosphopyridine nucleotide. I have achieved a ten-fold purification, involving dialysis, protamine and ammonium sulphate fractionation, of the α,ε-diaminopimelic acid synthesizing complex without demonstrating the need for additional co-factors. The abstract of Peterkofsky and Gilvarg[73] indicated a 150-fold purification of the N-succinyl-ε-ketopimelic-glutamic transaminase; but did not mention a pyridoxal phosphate requirement for this system.

Experiments similar to those described by Abelson *et al.*[65] have been interpreted by Meadow and Work[74] to indicate two pathways of α,ε-diaminopimelic acid biosynthesis. These conclusions were based on the fact that *E. coli* 26-26 grown with unlabelled glucose and aspartate labelled with carbon-14 and/or pyruvate incorporated radioactivity into cellular α,ε-diaminopimelic acid but not in the exogenous α,ε-diaminopimelic acid. Use of trace amounts of labelled acetate under the same conditions, however, resulted in radioactivity in both the cellular and extracellular α,ε-diaminopimelic acid. These observations and the fact that extracellular α,ε-diaminopimelic acid was not produced until the period of maximum growth was attained enabled the above authors to conclude that cellular α,ε-diaminopimelic acid was synthesized by one metabolic pathway and that extracellular α,ε-diaminopimelic acid was synthesized from different precursors.

These studies do not negative any of the findings on α,ε-diaminopimelic acid biosynthesis described above; but it would appear that further investigations will be necessary to establish with certainty that two different synthetic pathways for α,ε-diaminopimelic acid are operative.

Elucidation of the steps involving activation of succinate, aspartate and pyruvate and the identification of all the components in this metabolic sequence, as well as the many aspects of α,ε-diaminopimelic acid metabolism still to be investigated; activation and incorporation into peptides and bacterial cell walls, its role in lipopolysaccharide complexes and the specific function of each isomer, will provide a very interesting field of study.

Added in proof. Gilvarg (*J. Biol. Chem.*, 234, 2955; 1959) has reported a more detailed account of the production and isolation, as well as the chemical synthesis, of N-succinyl-L-diaminopimelic acid. Contrary to his previous report[68], he indicates that N-succinyl-L-diaminopimelic acid is actually produced by mutant *E. coli* D-1$_{(\alpha)}$. Rhuland and Hamilton (*Biochim. Biophys. Acta*, 36, 559; 1959) report that *E. coli* 173-25, the α,ε-diaminopimelic acid auxotroph, contains all the enzymes necessary to synthesize α,ε-diaminopimelic acid. In addition to the synthesis of LL-diaminopimelic acid by this organism, another substance, presumably N-succinyl-diaminopimelic acid, is produced.

LETTERS TO THE EDITORS

ASTROPHYSICS

Low-Energy X-Rays from Interplanetary Space

It is generally believed that the Sun is a source of highly ionized gas which streams outward through the solar system at all times and in all directions[1]. At the orbit of the Earth, even under the quietest solar conditions, the velocity and density appear to be of the order of 500 km./sec. and 10^2 to 10^3 particles/cm.^{3} respectively. (When the Sun is very active velocities greater than 1,500 km./sec. and densities up to 10^5 cm.^{3} may be produced sporadically.) Theoretically[2], it is expected that this steady gas stream will finally become unstable at some radial distance from the Sun and establish a region of highly disordered interplanetary magnetic field and plasma.

I wish to point out that energy interchange processes between the heavy ions and the electrons of the plasma which may be expected to occur in this disordered region of hydromagnetic turbulence should lead to a diffuse source of low-energy cosmic X-rays which may be observable at altitudes greater than about 120 km. Exchange processes available, in addition to the Fermi and betatron acceleration mechanisms, include excitation of plasma oscillations[3] and a general process described by Veksler[4] which may operate as a plasma encounters any inhomogeneous magnetic field. The Veksler mechanism can, in principle, lead to complete interchange of energy between the protons and the electrons of the streaming solar plasma, producing thereby electrons with energies somewhat in excess of 1 keV. The total energy W_γ in the form of bremsstrahlung photons radiated by these electrons per c.c. of the disordered region, if only $Z = 1$ ions are considered, is given by:

$$W_\gamma = 11 \cdot 9 \times 10^{-20} N^2 \overline{T}^{\frac{1}{2}} \text{ ergs/cm.}^3\text{/sec.}$$

Presence of He and higher Z ions in the interplanetary gas will be neglected although such ions can probably contribute appreciably to the radiated power. $\overline{T}$ is the average energy of the electrons in ergs.

I now consider only photons between T and αT, where α is an instrumental cut-off, taking the electrons to be mono-energetic with energy T. The total number of such photons arriving near the Earth may be computed if we assume spherical symmetry, a disordered region extending radially[2] from 2 to 5 A.U., and complete energy exchange (without the inverse process) over a distance short compared to the thickness of the disordered region. Absorption is negligible since the total Thompson scattering probability in a path 1 A.U. in length is only $\sim 10^{-7}$. Under these conditions, the X-ray number flux F_γ near the orbit of Earth is given by:

$$F_\gamma = \frac{11 \cdot 9 \times 10^{-20} \log_e\left(\frac{1}{\alpha}\right)}{T^{\frac{1}{2}}} \, a^4 \int_{2a}^{5a} N_0^2 \, r^{-4} \, dr$$

where a is the Sun–Earth distance $= 1 \cdot 5 \times 10^{13}$ cm. = 1 A.U. and N_0 is the plasma particle density near the Earth.

If we consider X-rays between 10 and 50 Å., which may be readily measured with rocket or satellite-borne proportional counters, then $\alpha \approx 0 \cdot 2$ and with $N_0 = 10^2$ we find $F_\gamma \simeq 23$ X-rays/cm.^{2}/sec. corresponding to an energy flux of $\sim 3 \times 10^{-8}$ ergs/cm.^{2}/sec. Note that if N_0 is closer to 10^3 than 10^2 the flux will be $\sim 3 \times 10^{-6}$ ergs/cm.^{2}/sec. or $2 \cdot 3 \times 10^3$ photons/cm.^{2}/sec. (Radiation which may originate from individual streams of exceptional velocity and density such as are produced during periods of great solar activity is discussed elsewhere. Reiffel, L. (to be published).) These are, of course, upper limits to the flux, on the assumption that complete energy transfer occurs, which is obviously improbable. However, on the night side of the Earth, provided background radiation from celestial sources is not serious, rather high sensitivity might be achieved, hence the radiation may be detectable even in the event of a low energy interchange efficiency. Solar background radiation, backscattered into the detectors, would be low because of the small total scattering probability per A.U. mentioned earlier. Collimated detectors might be used to advantage to look for structure, for example, higher intensity in the plane of the ecliptic or 'patchiness' in the interplanetary gas X-ray source, and to discriminate against stellar backgrounds and auroral X-rays from the Earth.

To my knowledge, the only experimental information on X-rays in the night sky is the negative result obtained in a measurement briefly mentioned by Friedman[5] and obtained in the course of the N.R.L. rocket programme. The upper limit, established by the lack of a measurable flux, in this case was 10^{-8} ergs/cm.^{2}/sec. per Å. in the region around 50 Å. The counters used for the measurement were presumably of the type described by Byram *et al.*[6] and, as such, were more appropriate to detecting the high fluxes associated with direct exposure to solar X-rays. The upper limit quoted above corresponds to an energy flux, calculated on the basis of a thin target bremsstrahlung spectrum, of about 2×10^{-6} ergs/cm.^{2}/sec. over the wave-length range 10–50 Å. This is just about the upper limit calculated for the X-rays of interplanetary origin on the assumption of the higher gas density. Presumably counters specifically designed for this task could be made a great deal more sensitive since the effective area of the counters used by Byram *et al.* was only of the order of $0 \cdot 05$ cm.^{2} while the efficiency was about 5 per cent.

The possibility of observing radio noise from the mechanism described above will be discussed in a subsequent communication.

GEOPHYSICS

Observations on the Solar Eclipse of October 2

During the recent solar eclipse of October 2, 1959, measurements were made at the U.S. Air Force Cambridge Research Center's radio astronomy site at Hamilton, Massachusetts. At this location the Sun rose partially eclipsed and 10 min. later it was totally eclipsed at an elevation of about 1°.

Having tracked the Sun from sunrise for a week prior to the eclipse, average refraction corrections were worked out to permit accurate antenna pointing and tracking of the Sun.

Measurements were made simultaneously at 224 and 1,300 Mc./s., using an 84-ft. paraboloid, and at 3,000 Mc./s. using an 8-ft. dish located 80 ft. east of the 84-ft. antenna.

Information was obtained from the records of the eclipse and in comparison with records of days both before and after the eclipse (control days).

On the eclipse day, the Sun was quiet. In fact, it was at its coldest level for the two weeks observed. However, interferometric solar maps at 3,000 Mc./s. (R. Bracewell, personal communication), at 9,300 Mc./s. (J. F. Denise, personal communication) and at 1,420 Mc./s. (W. N. Christiansen, personal communication) indicate the presence of plage areas on both the east and west limbs of the Sun. From this, one would expect the apparent solar diameter to be larger than the quiet Sun in the shorter wave-length region, with high-intensity levels extending beyond the solar disk.

This accounts for the fact that the residual energy recorded at totality at both 3,000 Mc./s. and 1,300 Mc./s. of 20 per cent of the uneclipsed Sun is greater than the signals recorded during low sunspot cycle year eclipses. At 224 Mc./s., however, with radiation originating in the corona little affected by the plage areas, and with interferometric maps plotted at this frequency-range at Nançay, France, for example, indicating no point source of solar activity, the residual energy-level of about 35 per cent at totality was not unlike the value for low sunspot cycle year eclipse records.

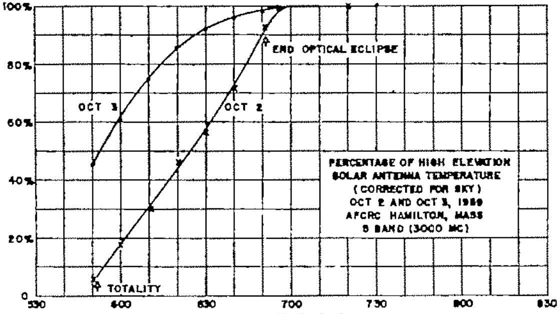

Fig. 1

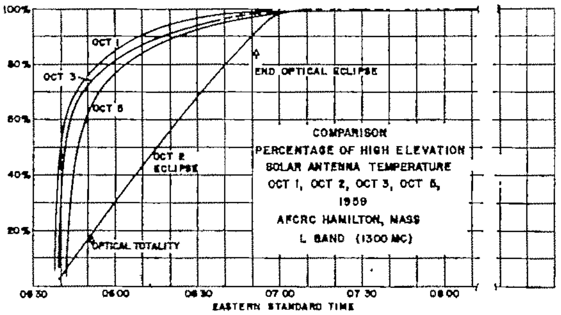

Fig. 2

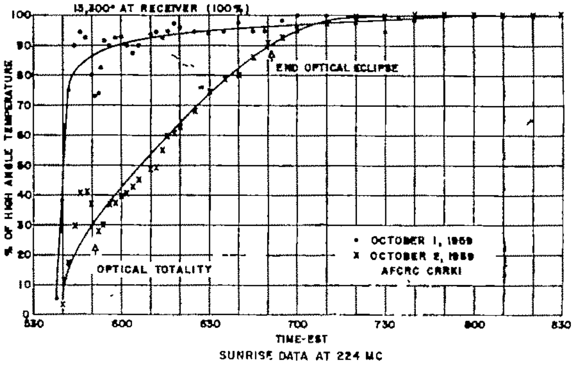

Fig 3

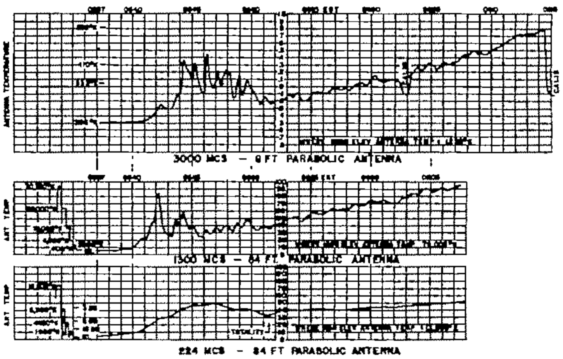

Fig. 4

Energy-levels during the recent eclipse are plotted in Figs. 1, 2 and 3.

Fig. 4 is a record of the signals received in the early part of the eclipse period. Since totality occurred when the Sun's elevation was approximately one degree, low-angle effects were evident. Large scintillations were seen starting at about 0542 E.S.T., especially at the higher frequencies. At this time, the Sun was rising with the east limb as yet uneclipsed. Two radio-frequency active plage areas in this region account for the high-amplitude scintillations. Normally with an uneclipsed solar disk the active plage areas act as point sources and at elevations up to 4 or 5° produce fairly deep fluctuations as, indeed, they did on all days observed. However, none could approach the violence of the 1,300 Mc./s. fluctuation at 0542 E.S.T., Oct. 2, 1959, in terms of percentage of antenna temperature, which was 5 or 6 times the mean curve temperature. Throughout the entire period illustrated, scintillations were high due to early covering and later uncovering of point sources on the Sun with scintillations existing even during 'totality'.

Individual fluctuations at 1,300 Mc./s. and 3,000 Mc./s. were remarkably well correlated in detail, in spite of the separation of the two antennæ and the difference in size of antenna apertures. Thus the peaks and nulls of one frequency are well matched by the other throughout the entire control period.

During the control period, no scintillations were recorded at 224 Mc./s. This is consistent with the quiet nature of the Sun and its large angular diameter at this frequency.

From the scintillation records, two points are evident. The first—the shadow patterns at 1,300 Mc./s. and 3,000 Mc./s. (generated by the radio-frequency active areas on the Sun, which interfering with one another normally decrease the amplitude of the scintillations) are not dependent on frequency. This point is somewhat at variance with work reported by Kazès[1]. The second—within the distance between the centres of the two antennæ, a single shadow pattern exists. This latter observation is generally in accord with work of Steinberg and Kazès[2].

A more detailed analysis of the eclipse and scintillation data will appear at a later date.

Rare Hiss, Earth Currents and Micropulsations on November 27, 1959

ON November 27, 1959, a rare signal was heard on the chorus-whistler equipment[1] at College, Alaska. Beginning as a whistle of perhaps 2 kc./s. at approximately 1351 A.S.T. (2351 G.M.T.) on November 27, 1959, a tone rose slowly to about 10 kc./s., becoming a hiss lasting for what seemed to be several minutes. At the same time magnetic field micropulsations[2] with periods of 10–20 sec. were initiated with a commencement magnitude of about 2·5γ falling to 0·4γ in about 5 min.

An unusually abrupt sudden commencement on the Earth current record[3] at College was also observed at 1351 A.S.T. Although sudden commencements are not rare in the Earth current records, they are usually preceded by some sort of activity. During the hour before the sudden commencement the maximum range of activity in the geographical north–south component was 16 mV./km. At 1351 the trace was abruptly displaced—572 mV./km. In less than 30 sec. the trace recovered and went + 410 mV./km. A negative deflexion of the trace corresponds to a northerly directed electron current in the Earth. For the next 3 hr. the trace oscillated about 150 mV./km. with a dominant period of about 2 min. Strong activity continued through the night, and storms occurred during the next two nights.

A red auroral arc was observed later that day commencing in the north about 1645 A.S.T., reaching the zenith at about 1720 and fading by 1745.

Continental Drift

IN recent years the question of continental drift has received renewed attention mainly as a result of palæomagnetic studies. The general consensus of opinion appears now to look with favour upon this hypothesis. No attempt will be made here to summarize all the supporting evidence—rather the purpose of this communication is to point out a difficulty with such a theory. This is based in part on measurements of the flow of heat through the Earth. Certainly far too few heat-flow measurements have been made to draw any quantitative conclusions. Nevertheless, in spite of quite a large range in the measurements of the flow of heat through the ocean floors, the average flow from oceanic and continental areas is approximately the same. There are also many cases where the oceanic flow of heat is greater than the average value through the continents. These results were unexpected on the basis of the radioactive content of typical oceanic and continental crustal rocks existing near the Earth's surface.

It is a very real problem to find sources of heat beneath the ocean floors. The whole of the observed continental heat flow could be produced by the uranium, thorium and potassium contained in about 25 km. of granite. Granitic type rocks are almost completely absent under the oceans—typical oceanic rocks being basalt the radioactive content of which is only about 30 per cent of that of continental rocks. Bullard, Maxwell and Revelle[1] have shown that heat production in the sediments due to biological activity, radioactivity and other processes such as chemical weathering cannot account for more than 1 per cent of the observed values. Again, the oceanic crust, being relatively thin and composed mainly of basaltic materials, can produce at most 10 per cent of the observed values. The remaining heat must therefore come from the mantle. There is thus a striking difference between the mantle under the oceans and under the continents. Hence, if a continent, with its more radioactive crust, were to drift over an oceanic area, with its more radioactive mantle, much higher continental heat flows than are observed would be expected.

The distribution of heat sources in the mantle under the oceans is quite critical if melting at depth is to be avoided. A distribution of radioactivity to depths greater than 200 km. would lead to temperatures above the melting point. On the other hand, a distribution of radioactivity through the upper 200 km. of the mantle would require a much greater radioactive concentration than that found in ultrabasic rocks or stony meteorites. A deeper distribution of radioactive heat sources without producing melting would be possible if rocks at depth have a much higher thermal conductivity than is generally assumed, or by convection in the mantle.

It may be argued that the variations observed in the oceanic heat flow are due to convection currents in the mantle. Thus, for example, the recent high values found by Von Herzen[2] along the East Pacific Rise with areas of low heat flow flanking it may be due to a large convective cell in the upper part of the mantle. But if such an explanation is true, it is difficult to see why convection cells should be confined to the oceanic mantle and not be present under the continents, where the average heat-flow values show considerably less variation.

The concentration of uranium, thorium and potassium in the outer layers of the Earth must have occurred during its very early history (whether a hot or cold origin is postulated), the thickness of this outer layer being a few hundred km. The mantle under the oceans is thus presumably 'primeval', while that under the continents is 'anomalous'. However, the continents were formed, whether initially or whether, as advocated by Wilson[3], for example, they have grown from nuclei throughout geological time drawing their material from the mantle, the fact remains that the constitution of the upper part of the mantle is at present very different beneath the oceans and beneath the continents. It is this fundamental difference that makes it very difficult to see how continental drift can have occurred —unless the continents drag the upper few hundred km. of the mantle along with them, which seems extremely unlikely.

Isotopic Distribution in a Greenland Iceberg

THE heavy-oxygen content in the ice of the Greenland ice cap is extremely low[1-3]. This is part of a common feature showing decreasing $H_2{}^{18}O$ content in fresh water when going towards a colder climate[1].

At a given location the seasonal variation in temperature causes a similar variation in the heavy-oxygen content of the precipitation[3,4]. On the Greenland ice cap, where the precipitation accumulates, this latter variation has been refound by investigation of stratigraphical series of snow and ice samples from a borehole 400 m. deep[3]. Parallelism between the deuterium and oxygen-18 content has been shown in snow samples from the Greenland ice cap[5]. The present work shows this parallelism to be conserved in the ice during several hundred years.

The samples investigated were collected during the North American Arctic Institute Greenland Expedition 1958 headed by Dr. P. F. Scholander. The deuterium analyses were made at Centre d'Etudes Nucléaires de Saclay by the technique described in ref. 6, while the oxygen-18 measurements were carried out at the University of Copenhagen by the technique described in ref. 7.

The samples were all taken from one piece of ice emitted from the Ingnerit glacier in West Greenland (70·9° N.). This piece was part of a larger amount of ice the average age of which has been determined by Scholander and co-workers by means of the carbon-14 method using the technique described in erf. 8. The piece of ice in question was white with mostly round bubbles. Three parallel layers of clear ice were situated 33 and 25 cm. from each other. The samples were taken along a line perpendicular to these layers.

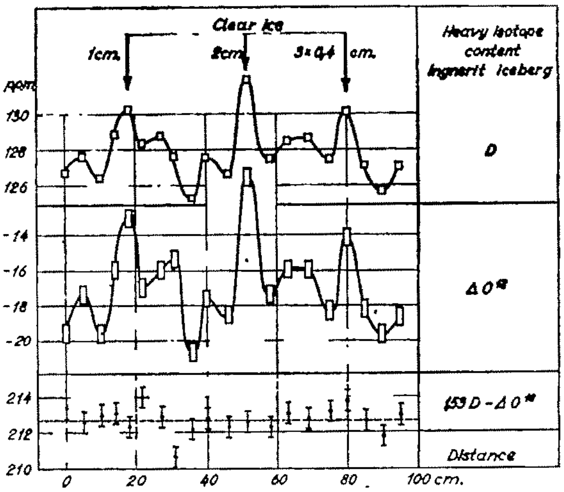

Fig. 1

In Fig. 1 the deuterium content (D) and the deviation of the oxygen-18 content (ΔO^{18}) of the sample from a standard are plotted in units of p.p.m. against the distance of the sample from an arbitrary zero point. In the lower part of Fig. 1 the relation between D and ΔO^{18} is seen to be linear within the measuring accuracy. With the use of our particular standard for oxygen-18 the linear relation is $1 \cdot 53 \text{ D} - \Delta O^{18} = 212 \cdot 7$. This shows complete parallelism between the variations in deuterium and oxygen-18, and, furthermore, conservation of isotopic anomalies in the ice during several hundred years.

The highest heavy isotope contents are found in the parallel layers of clear ice probably originating from summer-melting at the time of formation of the ice. This is due to evaporation from the wet snow; the light isotopic component of the water being the most volatile one.

We wish to thank Dr. P. F. Scholander and Dr. J. Koch for their interest in the work. The project was sponsored by the Arctic Institute of North America with principal support from the U.S. Office of Naval Research. Financial support was also granted by Statens almindelige Videnskabsfond, Copenhagen.

PHYSICS

A Very General Class of Exact Solutions in Concentration-dependent Diffusion

THE mathematics of concentration-dependent diffusion has been found in recent years to be important in problems of diffusion in polymers[1–3] and in the problems of the transport of water in its various phases in soils and other porous materials[4–7]. Almost without exception, it has been necessary to use numerical methods to secure the necessary solutions[2,3,8,9]. According to Crank[10], the only known 'formal solutions' are due to Fujita[11,12]. They provide solutions of the equation:

$$\frac{\partial\theta}{\partial t} = \frac{\partial}{\partial x}\left(D(\theta)\frac{\partial\theta}{\partial x}\right) \qquad (1)$$

subject to the conditions:

$$\begin{aligned} \theta = 0,\ \ x > 0,\ \ t = 0\,, \\ \theta = 1,\ \ x = 0,\ \ t > 0\,; \end{aligned} \qquad (2)$$

and are for the following $D(\theta)$ functions:

$$D = D_0/(1-\lambda\theta);\ D = D_0/(1-\lambda\theta)^2;$$
$$D = D_0/(1 + 2a\theta + b\theta^2).$$

Here we report the existence of a very general class of $D(\theta)$ functions which yield exact solutions of (1) subject to conditions (2). Fujita's $D(\theta)$'s are contained in this class. A similar very general class of $D(\theta)$ functions yields exact solutions of (1) subject to another set of practically important governing conditions:

$$\theta = 0, x > 0 \text{ and } \theta = 1, x < 0, t = 0;$$
$$\int_0^1 x\,d\theta = 0, t \geqslant 0. \qquad (3)$$

The substitution:

$$\varphi = xt^{-1/2}$$

enables (1) subject to (2) or (3) to be reduced to[8]:

$$\int_0^\theta \varphi d\theta = -\ 2D\,d\theta/d\varphi.$$

That is:

$$D = -\ \tfrac{1}{2}\int_0^\theta \varphi\,d\theta\,.\,d\varphi/d\theta.$$

It follows that the solution of (1) subject to (2) or (3), $\varphi(\theta)$, will exist in exact form, so long as $D(\theta)$ is of the form:

$$D = -\ \tfrac{1}{2}\int_0^\theta F\,d\theta\,.\,dF/d\theta, \qquad (4)$$

where F is an analytical (I use this adjective to describe infinitely differentiable functions of real variables) function of θ which satisfies the following conditions: (*a*) the integral $\int_0^\theta F\,d\theta$ exists; (*b*) $dF/d\theta \leq 0$; (*c*) for (1) subject to (2), $F(1) = 0$; (*d*) for (1) subject to (3), $\int_0^1 F\,d\theta = 0$. (Note that D will be expressible in terms of known functions so long as F is integrable in terms of known functions.)

A very large class of F functions satisfies these conditions, so that, accordingly, there exists a very large class of D functions which lead to exact solutions of (1) subject to the appropriate conditions. There is thus an *embarras de richesse* of exact solutions available. A few very simple results are given in Tables 1 and 2.

Table 1. SOME SIMPLE CASES OF EXACT SOLUTIONS OF (1) SUBJECT TO (2)

D	φ	Remarks
$\frac{n}{2}\theta^n\left(1-\frac{\theta^n}{1+n}\right)$	$1-\theta^n$	$n > 0$
$\frac{n}{2}\theta^{-n}\left(\frac{\theta^{-n}}{1-n}-1\right)$	$\theta^{-n}-1$	$0 < n < 1$
$\frac{1}{2}\sin^2\frac{\pi\theta}{2}$	$\cos\frac{\pi\theta}{2}$	
$\frac{1}{2}e^{2-\theta}(1-e^{-\theta}-\theta/e)$	$e^{1-\theta}-1$	

Table 2 SOME SIMPLE CASES OF EXACT SOLUTIONS OF (1) SUBJECT TO (3)

D	φ	Remarks
$\frac{n\,(n+1)}{2}\theta^n\,(1-\theta^n)$	$1-(n+1)\,\theta^n$	$n > 0$
$\frac{n}{2\,(1+n)}[(1-2\theta)^{n-1} - (1-2\theta)^{2n}]$	$(1-2\theta)^n$	$n = 1, 3, 5, 7, ..$
$\frac{n}{2\,(1-n)}\theta^{-n}\,(\theta^{-n}-1)$	$\theta^{-n}-\frac{1}{1-n}$	$0 < n < 1$
$\frac{e^\theta}{2}[(e-1)\theta+1-e^\theta]$	$e-1-e^\theta$	

To this point we have developed these ideas under the restriction that F be analytical. However, the existence of D as a continuous function requires merely that F be differentiable once. Further, if a finite number of discontinuities in D is allowable, we may permit F to be not differentiable at a finite number of points in the θ-interval. That is, F may consist of a finite number of different analytical functions of θ, each covering a separate part of the θ-interval. The scope for using analytical methods is therefore even wider than might appear at first glance.

The range of exact solutions is so great that the $D(\theta)$ functions encountered in practical applications should be capable of accurate representation by the form (4). It would therefore seem that foundations have been provided for placing the theory and practice of much of the mathematics of concentration-dependent diffusion on an analytical basis. These matters are treated further in papers in the press in the *Australian Journal of Physics*.

GEOLOGY

Presence of Carbohydrates and Other Organic Compounds in Ancient Sedimentary Rocks

MOST investigators have been of the opinion that proteinaceous and carbohydrate materials that are deposited in marine and lake sediments cannot survive for long periods of time but are rapidly decomposed. However, in recent years several investigators have shown the presence of amino-acids in Tertiary shales[1] and in fossil shells and bones as old as the Devonian[2].

Preliminary studies have now demonstrated the presence of minute amounts of carbohydrate as well as proteinaceous substances in bituminous sedimentary rocks ranging in age from Ordovician to Tertiary. The reducing environment under which these sediments accumulated, coupled with the association between the organic compounds and finely divided inorganic matter, probably account for the preservation of these compounds.

Outcrop and well-core samples were thoroughly cleaned by immersion in chromic acid and subsequent washing with water. After being powdered, each sample (about 500 gm.) was treated with 0·5 *N* sulphuric acid for 8–10 hr. on a boiling water-bath. The hydrolysis mixture was neutralized with barium carbonate and freed from inorganic matter by ethanol precipitation and by ion-exchange resins. The hydrolysate from each sample was concentrated *in vacuo* and examined by paper chromatography. The following sugars were tentatively identified: glucose, xylose and arabinose, and possibly galactose and rhamnose (see Table 1). The concentration of glucose, which was the dominant component, expressed in mgm./kgm. of rock sample, varied from 0·14 for the Simpson to 1·3 for the Marcellus sample. In certain of the rock samples there was some indication of the presence of glycerol.

The glucose (180×10^6–300×10^6 years old), isolated from the Leonard and the Marcellus formations by the above treatment, was separated by paper chromatography (solvent: pyridine–ethyl acetate–water (2 : 5 : 7)) and characterized as the D-isomer by transforming it into N-*p*-nitrophenyl-β-D-glucosylamine, m.p. and mixed m.p. 184° C., $[\alpha]^{20}_{D} - 200°$ (approx.) in pyridine (*c.* 0·1)[3].

The mode of occurrence of the carbohydrate compounds in the rock formations is not yet known.

Table 1. CARBOHYDRATE COMPONENTS OF SEDIMENTARY ROCKS

Formation	Age	Component sugars				
		Glucose	Galactose	Arabinose	Xylose	Rhamnose
Stonehenge	Ordovician	+		(? +)	(? +)	
Simpson	Ordovician	+	(? +)	+	+	
Upper Chambersburg	Ordovician	+		(? +)		
Marcellus	Devonian	+	(? +)	+	+	+
Woodford	Upper-Devonian	+		+	+	
Des Moines	Pennsylvanian	+		+	+	
Missouri	Pennsylvanian	+				(? +)
Leonard	Permian	+	(? +)		+	
Schuler	Jurassic	+		+	+	
Green River	Eocene	+	(? +)		(? +)	
Elko	Miocene	+				

The rock was treated with hot 0·5 *N* sulphuric acid and the sugars identified chromatographically.

It has been shown, however, that in the case of a sample from the Marcellus formation, extraction with water yielded about 10 per cent of the total carbohydrate material as the free sugars, arabinose, glucose and xylose; the remaining undissolved carbohydrate material may be present in the polymeric form.

The amino-acids present in the acid hydrolysates of several rock samples were also investigated by paper chromatography. In comparing two core samples of shale of late Palæozoic age, the highly fossiliferous one of Pennsylvanian age appeared to contain alanine, glycine, valine, glutamic acid, aspartic acid, proline, leucine, cystine and tyrosine, whereas the non-fossiliferous shale of Permian age yielded only one amino-acid tentatively identified as aspartic acid. The amino-acids in the Pennsylvanian sample may be derived from fossil shell fragments.

Control experiments showed that neither the sugars nor the amino-acids arose from the materials used in the isolation techniques. These organic substances are believed to be original constituents of the rocks, although in the outcrop samples, despite careful collection and cleaning treatment, the possibility of surface contamination cannot be completely ruled out at present.

Evidence for Tertiary Crustal Distortion in Mid-Argyll

REGIONAL deformation associated with the emplacement of Tertiary igneous rocks is well known in the British Isles. There appears to be some evidence in mid-Argyll, recorded on the one-inch maps of the Geological Survey of Scotland[1], which suggests that crustal distortion (broadly similar to that described from east Greenland by Wager and Deer[2]) may have occurred in this area during the Tertiary. This distortion is now reflected by a change in the trend of the Old Red Sandstone minor dyke swarm, the north-north-east–south-south-west tear-faults and, also, by variations in the strike of the Dalradian country-rocks; the district over which this change takes place coincides with the path of the Tertiary dyke swarm centred on Mull.

The Old Red Sandstone dyke swarm of the south-west Highlands has a north-north-east–south-south-west trend for most of its length[3]. However, just to the south of Loch Etive[1], a slight swing is seen and the dyke swarm traces out a gentle arcuate curve (Fig. 1). In the Craignish–Kilmartin area, twenty miles south-south-west of Loch Etive, the dykes have returned to their north-north-east–south-south-west trend; the greatest deflexion of the dykes from their normal orientation is about 15°. It is of importance

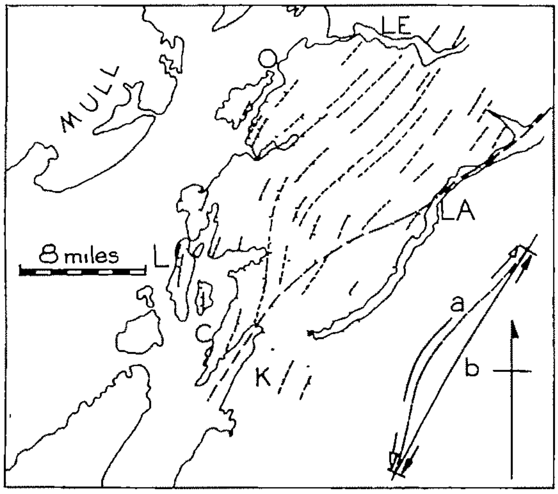

Fig. 1. Trend of Old Red Sandstone minor dykes (dashed lines) and Ericht–Craignish fault (alternately dotted and dashed line) Stippling represents the main zone of Tertiary dykes on the mid-Argyll mainland. The diagram in the lower right-hand corner illustrates the method of measurement of crustal extension (Extension = *a*–*b*/*b*). *LE*, Loch Etive; *O*, Oban, *LA*, Loch Awe; *C*, Craignish; *K*, Kilmartin; *L*, Luing

to note that the dyke swarm follows this arcuate trend, irrespective of whether the individual intrusions are emplaced into the Old Red Sandstone Lorne lavas or the Dalradian country-rocks. This same curving change in attitude is also shown by the Ericht–Laidon tear-fault which passes through Loch Awe to Loch Avich and Loch Craignish (Fig. 1); similarly, smaller tear-faults of the same set show a general arcuate swing. The strike of the Dalradian country-rocks and the axial trace of the Loch Awe syncline also appear to show the same change in trend (Fig. 2). It might be suggested that this flexure was developed in the Dalradian rocks during the Caledonian fold-movements and that the flexure then controlled the mode of emplacement of the later Old Red Sandstone dykes into both the Dalradian and the overlying Lorne lavas. This possibility appears unlikely because of the consistent north-north-east–south-south-west trend of the dyke swarm in the ground north-east of Oban[1]; in areas of Dalradian with variable strike, there is no change in trend of the dykes. Similarly, the arcuate swing in the Ericht–Craignish fault and other sub-parallel faults cannot be readily explained except by later deformation.

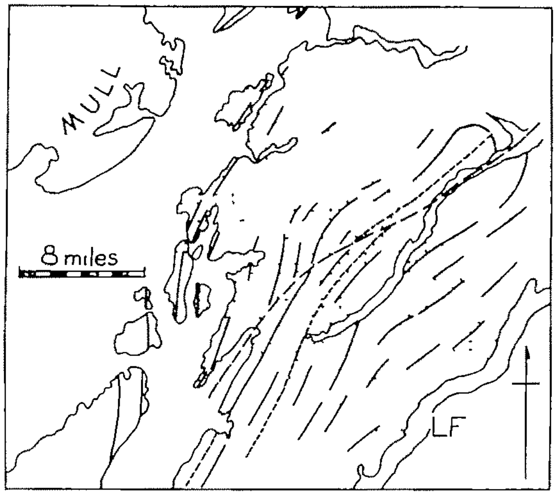

Fig. 2. Strike of the Dalradian country-rocks (solid lines) and axial trace of the Loch Awe Syncline (dashed line). Stippled area represents Mull Dyke Swarm. *LF*, Loch Fyne

It will be noted that (Figs. 1 and 2) the development of this arcuate structure is virtually restricted to the main zone occupied by the Mull Tertiary dyke swarm. The flexure appears to be dying out eastward and is scarcely recognizable near Loch Fyne (Fig. 2); there is, however, a slight curving in the Highland Boundary Fault where it is crossed by the Mull swarm, near Dunoon. Estimates of the crustal extension which might have been produced by the flexure can be made by comparing the distance along the arcuate trend of the flexure to that along the possible, undistorted trend: this is illustrated in Fig. 1. The estimate obtained in this way suggests a 3½ per cent extension between Luing and Oban and a 2½–3 per cent extension between Craignish and Loch Etive. These results can be compared to estimates, based upon actual measurements of dyke thicknesses, of a 4 per cent stretch along the south-east coast of Mull[2] and a 2½ per cent stretch along the western coast of Craignish[3].

I conclude that the coincidence in position between the arcuate flexure and the Mull dyke swarm is a strong indication that the flexure is the result of regional crustal distortion during the Tertiary.

CHEMISTRY

Chain Transfer in Mixed Solvent Systems

Chain transfer for solvents[1–4] in addition polymerization has attracted much attention, but scarcely any attempt has been made so far to determine the chain-transferring capacities of those substances which are immiscible in the monomer (say, water) or substances insoluble in the monomer, for example, such polymers as polyacrylonitrile. In the present work an attempt has been made to determine the transfer constants for such substances, keeping the whole system homogeneous in the presence of a third component.

The general equation for the reciprocal average degree of polymerization in the catalysed system can be easily derived[4] as:

$$1/\bar{P} = C_M + C_S(S)/(M) + C_I(I)/(M) + \ldots (A^2/(M)^2) \ldots R_p \quad (1)$$

where $\bar{P}$ is the number average degree of polymerization, C_M, C_S and C_I are the chain-transfer constants for monomer, solvent and initiator respectively. (S), (M) and (I) are concentrations of solvent, monomer and initiator respectively, whereas R_p is the rate of polymerization. A is a constant and is the ratio of the termination (k_t) and propagation constant (k_p); that is to say, $k^{\frac{1}{2}}_t/k_p$ for termination by coupling and $2k^{\frac{1}{2}}_t/k_p$ for termination by disproportionation. For our present purpose we have determ-

ined A from the slope of the plot of $1/\bar{P}$ against R_p in the polymerization of methyl methacrylate initiated by 2,2′azo*bis*-*iso*butyronitrile.

In the case where two solvents S_1 and S_2 are employed the equation may be transformed to :

$$1/P = C_M + C_{S1}(S_1)/(M) + C_{S2}(S_2)/(M) + R_pA^2/(M)^2 \quad (2)$$

If azonitriles are used as initiators the C_I of which are well known to be approximately zero, this can be further simplified to :

$$1/P = C_M + C_{S1}(S_1)/(M) + C_{S2}(S_2)/(M) + R_pA^2/(M)^2 \quad (3)$$

Now if the value of C_{S1} is known, this equation can be utilized to determine the value of C_{S2} provided the whole system is kept homogeneous. In that case :

$$C_{S2} = 1/(S_2)/(M) \ldots 1/P - C_M - C_{S1}(S_1)/(M) - R_pA^2/(M)^2 \quad (4)$$

To check the validity of equation (4) and the method proposed we have utilized a number of solvents as S_2, the chain-transfer constants of which have been determined very carefully by previous workers[3]. A number of sets of experiments were carried out with methyl methacrylate at 60° C. *n*-Butyl alcohol and methyl ethyl ketone were chosen as solvents S_1. The value of C_M has been taken from our previous work[5], and $\bar{P}$ was determined by viscometric measurements using the Ostwald type of viscometer from the relation $\bar{P} = K(\eta)^\alpha$. K and α have been taken from the work of Baxendale *et al.*[6]. Polymerization experiments were carried out by the sealing-tube method already described[2,3].

From our results represented in Table 1 it can easily be seen that the values of C_{S2} obtained by the present method compare favourably with values in the existing literature.

These results clearly show that the method suggested can be applied in evaluating chain-transfer constants for solvents. This opens up the possibilities of determining chain transfer for solvents immiscible with the monomer or in cases where the polymer separates out of the phase. Our present work relates to the chain-transferring capacity of water, the detailed results of which will be published in due course.

Nuclear Spin Resonance Spectrum of Isotactic Polystyrene

THE nuclear spin resonance spectrum of polystyrene has been reported by Bovey, Tiers and Filipovich[1]. Resonance peaks for *ortho* and for *meta* and *para* aromatic protons were observed. Absorptions by methylene and carbinyl (chain) protons appeared as a broader single peak in the case of high molecular weight species. For polystyrene of degree of polymerization 10 or less the carbinyl proton was resolved from that of the methylene protons.

We have now observed that carbinyl and methylene proton peaks are partially resolved also for high

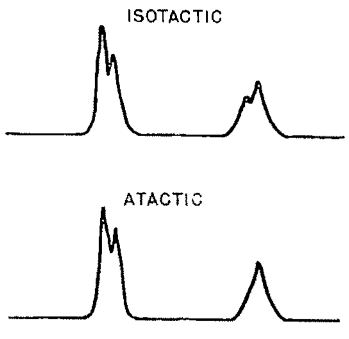

Fig. 1

molecular weight (10^5–10^6) isotactic polystyrene. The spectrum shown was obtained from isotactic polystyrene in deuterated chloroform using a 'Varian *V*–4300' 40·00-Mc./s. spectrometer. A similar spectrum was obtained in thionyl chloride. Like Bovey *et al.*, we observed no resolution of chain protons for commercial atactic polystyrene. Neither was resolution observed for high molecular weight (10^5) polystyrene prepared using *n*-butyl-lithium initiator nor for benzene-insoluble polystyrene obtained via Alfin sodium alkyl catalysis[2,3].

Dissolution of Chrysotile Asbestos in Water, Acid and Alkali

The dissolution of the asbestos mineral, chrysotile, $(OH)_6Mg_6Si_4O_{11}$, has been studied as a part of investigations into the nature of the industrial lung disease, asbestosis[1]. Because the results may be of value to industrial chemists and to geologists, and they explain apparently anomalous results which have been published[2,3], they are outlined here although the details and a discussion on their relevance to the problem of pneumoconiosis will appear elsewhere.

At 85–90° C. chrysotile gives an extract containing appreciable amounts of monosilicic acid and magnesium, for example, 0·5 gm. chrysotile in 100 ml. water gives 0·4 mgm. magnesium and 0·2 mgm. *ortho*silicic acid per 100 ml. solution after 15 min. When extracted with water at 25° C. for some days, chrysotile gives a very low concentration of silicic acid in solution but more than ten times that concentration of magnesium. If the asbestos is removed and the extract is heated to 85–90° C., the concentration of the dissolved silicic acid increases more than ten-fold although the magnesium concentration is unaffected. As an example, after 5 days, 1 gm. chrysotile in 200 ml. water at 35° gave an extract containing 1·1 mgm. magnesium and 0·1 mgm. *ortho*silicic acid per 100 ml. After heating for 3 hr. at 90° C. the extract contained 1·2 mgm. magnesium and 1·4 mgm. *ortho*silicic acid per 100 ml. It is thought that magnesium ions are leached from the chrysotile giving fragments of the two-dimensional sheets of the silicon–oxygen lattice which are resistant to water except at elevated temperatures, when they break down to give *ortho*silicic acid.

Hydrochloric acid (0·1 *N*) attacks chrysotile giving a solution containing *ortho*silicic acid and magnesium ions. Sodium hydroxide (0·1 *N*) scarcely attacks chrysotile, presumably because of a protective coating of hydrated magnesium ions on the surface of the fibres. If acid-washed chrysotile is extracted with sodium hydroxide, silica passes rapidly into solution but very little magnesium; the acid removes the protective layer, allowing the disintegration of the next layer of the silicon–oxygen lattice by the alkali. Evidently the behaviour of chrysotile depends on its history, and it is particularly vulnerable to alternating acid and alkaline conditions.

This communication describes a part of a programme of research which is proceeding under the auspices of the Asbestosis Research Council.

Clathrate Compounds in Chromatography

Partition and adsorption chromatography can be successfully applied for separation of mixtures of substances which differ in type and number of functional groups, or for separation of members of a homologous series. Less success was attained in separation of isomers. We therefore sought for a process which would be selective as regards the shape and size rather than the chemical properties of molecules.

The discovery of clathrate compounds suggested that inside their structure molecules of definite shape and size might be incorporated[1,2]. The first inorganic compound of that group was monoamminonickel cyanide[3,4], but many other complexes[5] of nickel, cobalt, manganese and iron with four basic nitrogen molecules and some anions around the metal ion followed. These compounds are said to be highly selective towards clathrate formation with organic molecules; and, more important, their selectivity depends rather on the shape of incorporated molecules than on their volume.

The selectivity, especially towards aromatic molecules, the small solubility of some complexes of that type, and other properties suggested the use of the formation of clathrate compounds for the separation of substances on the chromatographic column.

In preliminary experiments we filled the column with water-insoluble tetra-(4-methylpyridino)-nickel dithiocyanate prepared by the method of Schaeffer *et al.*[5]. Later, we found that another complex, prepared by using for precipitation a mixture of β- and γ-picoline and 2,6-lutidine instead of pure γ-picoline (so-called 3rd coal tar base fraction), has better properties.

One of the most important problems was to find an appropriate solvent composition for use as a mobile phase. We have used the mixture of γ-picoline or 3rd fraction with water containing some potassium thiocyanate.

To obtain high precision of results, we have used the chromato-polarographic method[6]. The compounds separated and incorporated were aromatic and aliphatic nitro-compounds.

In these conditions we have investigated the separation of isomeric nitrophenols, nitroanilines, chloronitrobenzenes and nitrotoluenes. In all instances quantitative separation of *ortho* from other isomers was obtained. The *ortho* isomers are found in the first fractions of eluate and can be very accurately determined polarographically. Using more concentrated solutions of potassium thiocyanate and 3rd fraction, *meta*- and *para*-isomers can be eluted. In some instances the mobile phase composition can be so chosen that it is possible to separate completely all three isomers in one process. We have used 2·5 *M* potassium thiocyanate in 10 per cent 3rd fraction

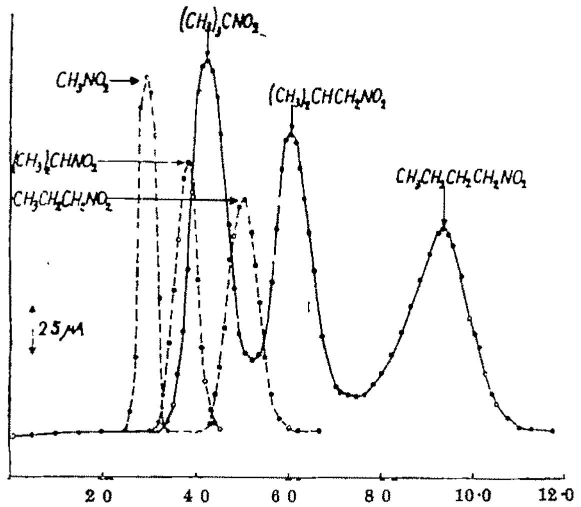

Fig. 1

base mixture for the separation of isomeric nitrophenols and nitroanilines (Kemula, W., Sybilska, D., and Geisler, J., unpublished work).

From nitroaliphatic compounds we have studied mixtures of 1-nitropropane and 2-nitropropane, 1-nitrobutane, 2-methyl-1-nitropropane and 2-methyl-2-nitropropane, but their separation is more difficult. No separation occurs when columns were filled with tetra-(4-methylpyridino)-nickel dithiocyanate or tetra-(3-methylpyridino)-nickel dithiocyanate. No insoluble complex could be prepared from pure 2,6-lutidine, but using the 3rd fraction base a very satisfactory column filling was obtained.

In Fig. 1 the continuous line indicates the separation of nitrobutanes, the dashed line indicates the elution of nitromethane and nitropropanes. The column height was 17 cm., its inner diameter 5·8 mm.; as an eluant we used 0·25 *M* potassium thiocyanate in 2 per cent 3rd fraction solution in water.

In Fig. 2 is shown for comparison the separation of the isomers using the reverse phase partition chromatography on powdered rubber[7]. As a stationary phase we used *n*-heptane, as a mobile phase 0·25 *M* potassium thiocyanate in 2 per cent 3rd fraction base mixture in water. The column height was 21·5 cm., the diameter 5·8 mm.

Our results show that the application of clathrate compounds in chromatography affords an excellent method for the separation of isomers. The mode of action of the complex prepared from 3rd fraction base mixture and the applicability of other complexes are being investigated. Such chromatographic studies may also be helpful in elucidating the properties of clathrate compounds and their structure.

BIOCHEMISTRY

Casein labelled with Iodine-131 as a Substrate for the Measurement of Trypsin and Chymotrypsin

THE spectrophotometric method of Kunitz[1] is a marked improvement over previous methods for the measurement of trypsin and chymotrypsin activity. This procedure involves a measurement of the optical density at 280 mμ of the trichloracetic acid-soluble products formed during the enzyme hydrolysis of casein; it becomes impractical, however, where large concentrations of 280 mμ absorbing materials are present, such as in sera. In this communication, a modification of this procedure will be described which utilizes casein labelled with iodine-131 as the substrate and the measurement of radioactivity as an estimate of enzyme activity.

Labelled casein is prepared in the following manner. Into 12 ml. of 0·1 *M* disodium hydrogen phosphate–potassium dihydrogen phosphate buffer (*p*H 7·60) is placed 1 gm. of Hammarsten casein (Hammersten casein from Nutritional Biochemical Corporation); trypsin (50 per cent magnesium sulphate, 2 × crystallized) and chymotrypsin (salt-free, crystallized) from Worthington Biochemical Corporation; radioactive iodine from Abbott Laboratories, specify chemically pure product). The protein is stirred into solution while heating in a warm water-bath and then heated for 15 min. in a boiling water-bath. After cooling the solution to room temperature, the flask is placed on a magnetic stirrer and the casein iodinated with the following solution. Into 1 ml. of a sodium iodide solution containing 1 mc. of iodine-131 is pipetted the following reagents: 0·3 ml. 0·01 *M* potassium iodate, 0·3 ml. 0·01 *M* potassium iodate, drop by drop 0·05 *M* hydrochloric acid until the sodium iodide–iodine-131 mixture turns faint yellow, followed by 0·5 ml. of 0·05 *M* hydrochloric acid. The orange-coloured radioactive solution is mixed thoroughly and then added dropwise to the stirring casein solution over a period of 10–15 min. Stirring is maintained at room temperature for an additional 45 min. The iodinated casein is then transferred to a dialysis bag and dialysed against four 700-ml. portions of 0·1 *M* phosphate buffer (*p*H 7·35) in the refrigerator. The resulting labelled casein has a specific activity of 15–20 μc./ml. for the final casein solution and constitutes a 20–25 per cent radiometric yield.

The specific activity of free iodine in the fourth dialysate, which is also representative of the free iodine-131 contaminate of the labelled casein, is only on the average of 1·0 mμc./ml. This constitutes approximately 0·005 per cent of the total iodine-131 in the final casein solution.

Stock casein, unlabelled and un-iodinated, is used for making the appropriate dilution of the labelled substrate and is prepared as above. For enzyme measurement, a 2 per cent casein solution containing 1 μc. per ml. is prepared in 0·1 *M* phosphate buffer (*p*H 7·35).

Stock solutions of trypsin and chymotrypsin are prepared as 250 μgm./ml. in 0·0025 *M* hydrochloric acid. Diluted solutions of 25 μgm./ml. in 0·0025 *M* hydrochloric acid are further prepared for actual use.

Enzyme measurement is carried out as follows: Into 12-ml. centrifuge tubes are pipetted varying amounts of trypsin or chymotrypsin contained in less than 1 ml. volume. The volumes are made up to 1·0 ml. with 0·0025 *M* hydrochloric acid, mixed, and pre-incubated in a 37·5° C. constant-temperature bath for 5 min. The 2 per cent casein solution labelled with iodine-131 is pre-incubated at the same time. 1-ml. volumes of the casein solution are added with stirring to the assay tubes at 1-min. intervals. A blank tube containing 1 ml. of 0·0025 *M* hydrochloric acid is treated similarly. After a 20-min. incubation period, 3 ml. of 5 per cent trichloracetic acid are added with stirring to stop the enzyme action. The stirring rods are carefully removed and the solutions left at room temperature for 1 hr. Following a 20-min. centrifugation at 1,700*g* and 25° C., the supernatants are poured from the tubes. 1-ml. volumes of the supernatants are pipetted into 1-dram, screw cap vials and the radioactivity therein measured in a well scintillation detector.

In Fig. 1 is shown a typical plot of corrected counts (corrected for coincidence loss and for counts obtained in the blank tube) versus μgm. trypsin per ml. of the 1 per cent casein digestion mixture. Measurements of the radioactivity in the supernatants have been found to correlate well with optical density measurements made at 280 mμ, as indicated in Fig. 1. Fig. 2 shows a similar curve obtained for the measurement of chymotrypsin activity by this method.

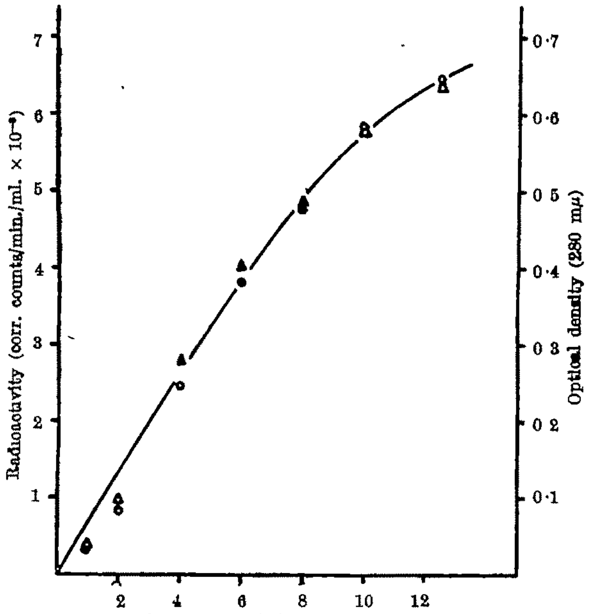

Fig. 1. Standard curve for digestion of casein labelled with iodine-131 by trypsin. Counts/min./ml (circles) in trichloracetic acid supernatant and/or optical density (triangles) plotted versus micrograms of trypsin protein

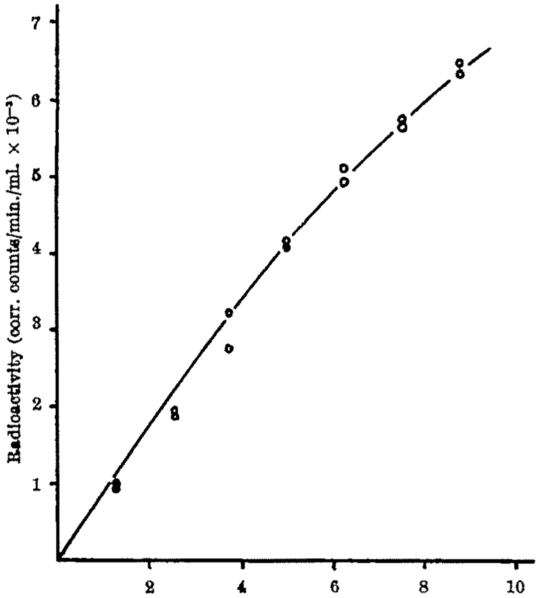

Fig. 2. Standard curve for digestion of casein labelled with iodine-131 by chymotrypsin. Counts/min./ml. in trichloracetic acid supernatant plotted versus micrograms of chymotrypsin protein

The use of a 2 per cent casein solution provides a linear relationship between enzyme activity and enzyme concentration over a greater range of enzyme concentration than is possible with the 1 per cent casein used by Kunitz[1]. Both 3 per cent and 4 per cent solutions serve to extend this linear relationship over a still further range of enzyme concentration. However, when using these more concentrated casein solutions, a relatively large amount of precipitate is obtained upon treatment with trichloracetic acid. Therefore, a correction should be made for the precipitates associated with each tube to obtain the correct curve representing enzyme activity.

This procedure utilizing labelled casein provides a sensitive means of measuring trypsin or chymotrypsin activity. Only those casein hydrolysis products which result directly from enzyme activity are measured. The spectrophotometric method could conceivably measure acid-soluble contaminants which absorb highly in the region of 280 mμ in addition to the casein hydrolysis products.

This method has been applied to the evaluation of the trypsin inhibitory capacity of sera of normal individuals and of patients in varying diseased states which are in part associated with altered trypsin metabolism.

Role of the Inducer in the Induced Synthesis of β-Galactosidase in *Escherichia coli*

INDUCED (adaptive) enzyme formation in micro-organisms has been the subject of numerous studies[1]. Although a great deal is known about the kinetics of the biochemical processes involved, the precise role of the inducer remains enigmatic.

Any hypothesis describing the mode of action of the inducer must account for the structural complementariness between the inducer and the enzyme elicited by the inducer. Yudkin's 'mass action hypothesis'[2], which postulates inducer-enzyme combination as the prime mover of induction, represents such an attempt. The mass action hypothesis implies that substances capable of inducing an enzyme have affinity for the enzyme. Furthermore, the hypothesis predicts a positive correlation between the relative affinity of an inducer for the induced enzyme and the efficacy of the inducer as inducer of the enzyme. These predictions have been tested employing several inducible enzymes and a number of inducers in bacteria and yeasts[3]. It was found that certain highly effective inducers had no, or low, affinity for the induced enzyme. For this reason and also on the basis of certain other findings apparently incompatible with a mass action mechanism of enzyme induction, it was suggested that the inducer exerts its effect not by combining with the enzyme directly but rather by combination with some other cellular constituent. This hypothetical inducer-cell complex, the 'organizer'[4,5], would then catalyse formation of the enzyme.

One of the most thoroughly analysed inducible enzyme systems is that of the β-galactosidase of *Escherichia coli*. Monod and his collaborators[6,7] in a study of the relationship between the affinity of non-metabolizable galactosides for the enzyme β-galactosidase and the effectiveness of the same galactosides as inducers of the enzyme found that thiomethyl-β-D-galactoside and the α-galactoside melibiose were both highly effective inducers of β-galactosidase but had very low affinity for the enzyme. Affinity for β-galactosidase was determined by measuring the inhibition of the hydrolysis of the test substrate *o*-nitrophenyl-β-D-galactoside by the other two galactosides. A cell-free enzyme preparation was employed. It has been shown, however, that cell-free β-galactosidase (or the β-galactosidase of bacteria treated with toluene) differs from the intact-cell β-galactosidase with respect to its kinetic behaviour[8]. It has also been found more recently[9] that concomitant with β-galactosidase synthesis, the induced bacteria develop the ability to concentrate galactosides intracellularly. In view of these findings it was decided to re-examine the relationship between the affinity of galactosides for β-galactosidase and their inducing efficacy by (*a*) measuring the ability of galactosides to inhibit the β-galactosidase activity of intact cells and (*b*) determining the inducing efficacy of the same galactosides in *E. coli* strain *ML* 3, a strain that is unable to accumulate galactosides[9], and in which galactosides enter the cell apparently by diffusion only[10].

Fig. 1 shows that thiomethyl-β-D-galactoside and melibiose inhibit intact-cell β-galactosidase activity (measured as *o*-nitrophenyl-β-D-galactoside hydrolysis) competitively. Intact-cell β-galactosidase activity was measured in *E. coli* strain *ML* 308, which forms β-galactosidase constitutively and also has the ability to concentrate galactosides intracellularly[9]. The reaction was carried out as described in an earlier publication[11]. Michaelis constants of K_s $1 \cdot 3 \times 10^{-3}$ M *o*-nitrophenyl-β-D-galactoside and K_i $3 \cdot 3 \times 10^{-3}$ M thiomethyl-β-D-galactoside and $2 \cdot 5 \times 10^{-4}$ M melibiose were obtained. Thiomethyl-β-D-galactoside and melibiose do then show considerable affinity for the β-galactosidase of intact cells.

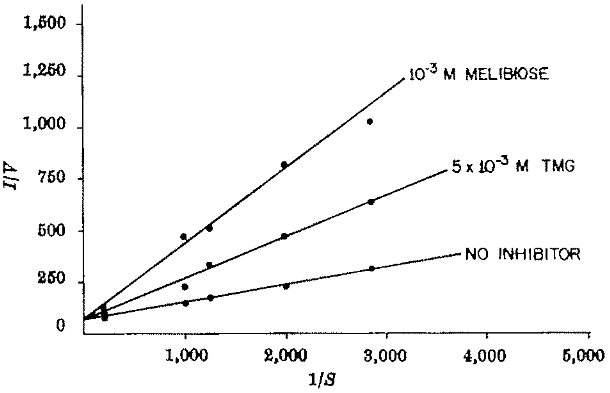

Fig. 1. Competitive inhibition of intact-cell β-galactosidase by thiomethyl-β-D-galactoside (TMG) and melibiose. Abscissa, reciprocal of *o*-nitrophenyl-β-D-galactoside concentration; ordinate, reciprocal of intact-cell β-galactosidase activity

The affinity of an inducer for the hypothetical enzyme-forming system may also be expressed as a constant $K_{s\,\mathrm{ind.}}$, where the latter term denotes that concentration of inducer which will induce a cellular concentration of enzyme that corresponds to half the maximal value obtainable, employing a saturating concentration of the same inducer and identical growth conditions. The $K_{s\,\mathrm{ind.}}$ for thiomethyl-β-D-galactoside and melibiose were determined in *E. coli* strain *ML* 3 by growing the bacteria from an inoculum of approximately 10^6 bacteria per ml. to a final population of approximately 10^9 bacteria per ml. in the presence of a series of inducer concentrations and determining the specific β-galactosidase activities of the cultures. Fig. 2 shows the $K_{s\,\mathrm{ind.}}$ for thiomethyl-β-D-galactoside to be $3 \cdot 5 \times 10^{-3}$ M and that for melibiose to be 2×10^{-4} M.

The finding that the affinities of thiomethyl-β-D-galactoside and melibiose for the enzyme β-galactosidase, when measured in the intact cell, are the same

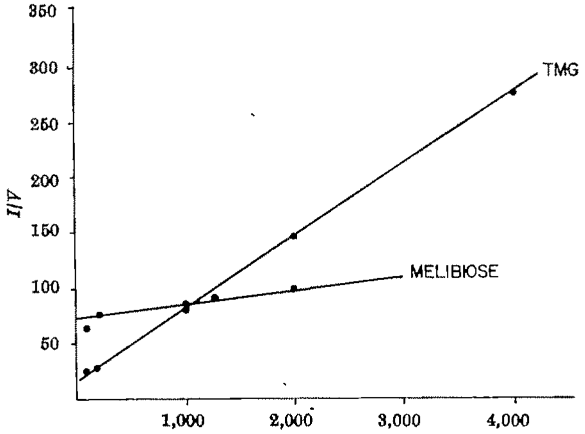

Fig. 2. Relation between the concentration of inducer present during growth and the specific β-galactosidase activity of the culture. Abscissa, reciprocal of inducer concentration; ordinate, reciprocal of specific β-galactosidase activity

as the affinities of thiomethyl-β-D-galactoside and melibiose for the enzyme-forming system is compatible with the hypothesis that enzyme induction involves combination between the inducer and the enzyme itself. The simplest scheme that would explain induced enzyme formation on this basis might be formulated thus:

$$X \text{ — enzyme} + \text{inducer} \rightarrow X + \text{enzyme — inducer}$$
$$\text{enzyme — inducer} \rightleftharpoons \text{enzyme} + \text{inducer}$$

where X denotes the enzyme-forming system. Combination of the enzyme with the enzyme-forming system X in the absence of inducer might then constitute 'repression' of enzyme formation[12].

An amplification of the proposed hypothesis of induced enzyme formation, an attempt to relate the phenomenon of inducible galactoside accumulation to the induction of β-galactosidase, as well as further experimental data bearing on the hypothesis will be published elsewhere.

I am indebted to the National Science Foundation for a research grant and to Mrs. Helen M. Talbott for expert technical assistance.

Ester-like Groups in Different Collagens and Gelatins

Gallop *et al.*[1] have recently reported the presence of ester-like links in several soluble collagens. We had also found such links in commercial acid-precursor pigskin gelatin and bovine hide corium collagen.

Gelatin was treated with 1·5 M hydroxylamine at pH 8·6 in water, 5 M or 8 M urea or 5 M lithium bromide at 4° C. for 1 or 5 days or at room temperature for 4 hr. Bovine hide corium collagen (prepared by washing with water and 8 per cent sodium chloride and acetone) was first soaked in 4 M sodium perchlorate for 24 hr., the supernatant filtered off and the residue soaked in 3 M hydroxylamine (25 ml./gm. of collagen) at pH 8·65 for 16 hr. at room temperature. Almost all the collagen dissolved except for a few small shreds. The solution was dialysed at 4° C. against water with mixed ion-exchange resins in the external compartment. The protein solution gelled. 80 per cent of the original collagen was obtained as gelatin.

Analyses for hydroxamate were carried out on the pigskin product by the ferric hydroxamate method of Lipmann and Tuttle[2] (acethydroxamic acid as standard) and by the method of Bergmann and Segal[3]. The bovine collagen was analysed by the latter method.

The hydroxamate content of the acid pigskin gelatin varied from 0·5 to 1·5 moles/10^5 gm. The results were the same for all the methods of treatment mentioned above. The hide collagen had a hydroxamate content of 2 moles/10^5 gm.

The starting pigskin gelatin has a number average molecular weight of 100,000 [4]. If one ester-like group were broken to yield two fragments of random size the average molecular weight would be 50,000. From measurements of intrinsic viscosity molecular weights of 25,000–35,000 were found, based on a viscosity–molecular weight relation established for this gelatin[4]. From melting points of 5 per cent gels, molecular weights of 30,000–70,000 were obtained, based on a melting point–molecular weight relation[4]. The discrepancy between the molecular weights by viscosity and melting point methods suggests that the reaction with hydroxylamine alters the shape of the gelatin molecules or changes the molecular weight distribution.

Hydroxamate values of 1–2 moles/10^5 gm. could be accounted for by carbohydrate; as little as 0·1 per cent would suffice. The differences between these values and the value of 10 moles/10^5 gm. found by Gallop *et al.* for soluble collagens suggest there may be differences related to whether the soluble or 'insoluble' collagen is used. There may also be differences resulting from species, tissue of origin and age of the collagen or the organism. Ageing organisms may contain increasing numbers of ester-like cross-links.

If water or sodium sulphate is used in place of sodium perchlorate, the collagen does not dissolve in hydroxylamine. Strong solutions of urea or sodium thiocyanate can be used in place of sodium perchlorate.

I wish to thank the Dean Langmuir Foundation, the Rockefeller Foundation, the Damon Runyon Memorial Fund, the New York Foundation and the Polytechnic Institute of Brooklyn for support. I am grateful to Drs. F. O'Flaherty and C. L. Deasy, University of Cincinnati, for the gift of the collagen.

Biosynthesis of Ergot Alkaloids

Five schemes for biosynthesis of the lysergic acid moiety of the ergot alkaloids have been proposed recently. All of them involve tryptophan or 5-hydroxytryptophan as precursors[1,2].

This communication deals with the effect of tryptophan, 5-hydroxytryptophan and its related compounds on the yield of total ergot alkaloids utilizing an *in vitro* culture of *Claviceps purpurea* to determine whether experimental evidence could be obtained to support one of the above schemes. A strain of *Claviceps purpurea*, *P.R.L.* 1578, was employed using Abe's medium[3].

Inoculation of the culture and the estimation of total alkaloids were carried out by a procedure slightly modified from that of Taber and Vining[4], and the composition of the total alkaloids was established by paper chromatography (ref. 5 and Weir, J. R., unpublished work). The R_F values of the spots found

Table 1. THE EFFECT OF TRYPTOPHAN AND 5-HYDROXYTRYPTOPHAN ON THE YIELD OF ALKALOID PRODUCTION

Age of cultures (day) Feeding	Age of cultures (day) Harvesting	Additives	Mgm./l.	Mgm. alkaloid/l. Supplemented	Mgm. alkaloid/l. Control	Deviation (per cent)
11	23	DL-tryptophan	48·4	0·21	0 25	−16
11	36			2·77	1·99	+39
11	23	DL-5-hydroxy-tryptophan	32·8	0·21	0·25	−16
11	36			0·99	1·99	−50
22	29	DL-tryptophan	48·4	0·65	0·97	−38
22	43			2·17	3·27	−33
22	29	DL-5-hydroxy-tryptophan	32·8	0·61	0·97	−38
22	43			2·42	3·27	−26
30	51	DL-tryptophan	96·8	6·92	4 29	+61
30	51		242·0	6·60	4·29	+54
30	51	DL-5-hydroxy-tryptophan	90·4	5·75	4·29	+34
30	51		226·0	5 07	4·29	+18

were identical with the R_F values of pure ergosine, ergosinine or ergotaminine, ergokryptinine, elymoclavine.

Tryptophan, 5-hydroxytryptophan, indole, 5-hydroxyindole, serotonin were added to the cultures of different ages (11, 22, 30 days) and sampled after certain intervals (23, 29, 36, 43, 51 days).

Table 1 shows that addition of tryptophan or 5-hydroxytryptophan did not change significantly the yield of total alkaloids even if the amount of added DL-tryptophan or DL-5-hydroxytryptophan was gradually increased. An equivalent amount of indole, 5-hydroxyindole and serotonin also did not cause marked difference in the total alkaloid production.

In another experiment a replacement culture technique was used. On the thirty-ninth day, when alkaloid formation was 1·2 mgm./l. in the control culture, the growth medium was decanted off, the remaining mycelium was washed thoroughly with sterile water (3 × 20 ml.) and the following new media were added under sterile conditions: (*a*) 1 gm. mannitol in 20 ml. water; (*b*) 1 gm. mannitol, 0·160 gm. succinic acid in 20 ml. water; (*c*) 1 gm. mannitol, 0·160 gm. succinic acid, 0·0048 gm. DL-tryptophan in 20 ml. water; (*d*) 1 gm. mannitol, 0·160 gm. succinic acid, 0·0045 gm. DL-5-hydroxytryptophan in 20 ml. water; (*e*) 1 gm. mannitol, 0·160 gm. succinic acid, 0·0048 gm. DL-tryptophan, 0·0045 gm. L-proline, 0·0045 gm. L-valine, 0·0045 gm. L-leucine in 20 ml. water; (*f*) 1 gm. mannitol, 0·160 gm. succinic acid, 0·0045 gm. DL-5-hydroxytryptophan, 0·0045 gm. L-proline, 0·0045 gm. L-valine, 0·0045 gm. L-leucine in 20 ml. water.

After an incubation period of 19 days the total alkaloids were estimated. The results given in Table 2 indicate that there is no marked difference in the amount of total alkaloids in the replacement cultures and the cultures grown in the Abe's media harvested on the same day (control culture).

These experiments emphasize the significant role of the age of mycelium on the amount of alkaloid production of *Claviceps purpurea*. This observation seems to be supported by another experiment, when the medium of the 21-day-old culture (at this time no measurable amount of alkaloid was yet formed in the control culture) was inoculated with fresh mycelium. After harvesting the culture on the fifty-first day, the amount of total alkaloid was negligible although the weight of the mycelium was as usual.

Table 2. THE EFFECT OF TRYPTOPHAN, 5-HYDROXYTRYPTOPHAN ON THE YIELD OF TOTAL ALKALOID PRODUCTION IN REPLACEMENT CULTURES

Medium	Mgm. alkaloid/l. Replacement culture	Mgm. alkaloid/l. Control culture
a	4·61	5·07
b	4·28	5·07
c	4·47	5·07
d	4·54	5·07
e	4·86	5·07
f	5·11	5·07

Although all our experiments indicate that tryptophan and 5-hydroxytryptophan are not directly concerned in the biosynthesis of lysergic acid alkaloids, it cannot be concluded that these amino-acids are not the direct or indirect precursors of lysergic acid alkaloids. It is possible that the metabolism of these amino-acids is much faster in other directions than in the formation of alkaloids; therefore, they have no significant influence on the yield of alkaloid.

While this work was in progress, Suhadolnik *et al.*[6] reported that labelled DL-tryptophan was not incorporated into ergonovine produced by *Claviceps purpurea* cultured on rye. More recently, Taber and Vining[7] reported that large amounts of L-tryptophan (500 mgm./l. culture medium) doubled the amount of total ergot alkaloids formed by *Claviceps purpurea in vitro*. These authors also observed that the addition of L-tryptophan resulted in the production of new types of alkaloids and tryptamine. A direct comparison of the results obtained by Suhadolnik *et al.* and Taber and Vining with ours is difficult due to the different experimental conditions. (During the preparation of this communication an abstract of a paper appearing in the Bacteriological Proceedings, Fifty-ninth General Meeting, St. Louis, Missouri, was kindly submitted by W. A. Taber and L. C. Vining. Although no detailed results were given in this abstract it was stated that a culture of *C. purpurea* when supplied with tagged DL-tryptophan produced labelled lysergic acid derivatives.)

Use of the sensitive radioactive tracer technique is definitely indicated to obtain more specific information on the biogenesis of these alkaloids. This work is in progress and will be published in the near future.

This work was supported by a grant, *A*-686, from the National Research Council of Canada. We wish to express our appreciation to Dr. A. Hofmann, Sandoz, Ltd., Basle, for samples of the pure alkaloids, and to Dr. W. A. Taber and Dr. L. C. Vining, Prairie Regional Laboratory, Saskatoon, Saskatchewan, for the culture *P.R.L.* 1578.

Glacial Acetic and Picric Acids as a Fixation for Gel Precipitation

DIFFICULTIES are often encountered in reading off immunological reactions on gel plates (cf. immunoelectrophoresis). The gel method, however, has many indisputable advantages over tube precipitation even if the latter is considered more sensitive quantitatively. The former has often been utilized for qualitative studies of the various components involved in immunological reactions. In this connexion it is often important to know whether or not the plate contains a precipitate which is not visible either macroscopically or microscopically (cf. interference microscopy). Various fixatives have been employed in order to detect or accentuate an immunological reaction before proceeding to qualitative studies. Acetic acid and alcohol in various concentrations have been most commonly used for this purpose.

During work on an immunological system in which one could *a priori* expect a very weak precipitation reaction several fixatives were tested. These were chosen with consideration of their physical and chemical effects upon the various components in the system. It appeared that a combination of glacial acetic acid and saturated picric acid solution was preferable in those instances in which a quantitative reading of a precipitation reaction involving mainly proteins is desired.

The most satisfactory combination was found to be 6 per cent glacial acetic acid and 94 per cent saturated picric acid solution ; $p\text{H} = 2 \cdot 1$. In these proportions the penetrating effect of acetic acid and the protein-precipitating effect of picric acid appear to advantage. These acids seem to complement each other in other respects as well. (At this *p*H the protein-precipitating effect of picric acid is good and *p*H is not appreciably altered by the precipitating reaction.)

If this method is to be used when serum forms one of the immunological components, the serum must be highly diluted. If this is not done, the gel plate must be washed before being fixed (cf. agar gel with serum added) otherwise interpretation is made impossible by the large amount of precipitate originating from the other serum proteins.

In addition to its sensitivity, the method described here offers other advantages such as a short fixation time and a result which can easily be interpreted and recorded.

Scanning of Paper Electrophoretograms after Protein Dyeing with Bromocresol Green

THE blue colour of bromocresol green-dyed protein developed by exposure to ammonia vapour is not stable, and elution of the dyed protein has been used to obtain an electrophoretic curve from paper electrophoretograms of serum dyed with bromocresol green. One disadvantage of this is that the paper strip is destroyed when it would have been of value as a record for reference.

The use of an agent other than ammonia vapour was investigated with the view of stabilizing the blue colour of such dyed protein so that scanning could be carried out.

An organic base, with which the strip could be easily impregnated, strong enough to develop the blue colour of bromocresol green and which was miscible with the scanning oil, was looked for. Of several which were tried diethylamine was found to be suitable and the following method of use was found satisfactory.

The electrophoretograms were dried and then dyed according to the method described by Franglen and Martin[1]. The dry strips were then dipped in a solution of 10 per cent v/v solution of diethylamine in diethyl ether. The ether was allowed to evaporate and the blue colour of the bromocresol green-dyed protein developed. A series of dyed strips can be brought to this stage ready for scanning. The strips were then oiled for scanning using the mixture described by King and Wootton[2].

Scanning was carried out using an *E.E.L.* scanner with an Ilford 205 filter. After scanning, the oil and diethylamine were removed from the strips with either a 1 : 1 mixture of acetone and diethyl ether or benzene. The acetone used must be free from water otherwise diffusion of the dyed protein bands will occur. The strips were then air-dried ready for storage.

It was found that the blue colour remained stable for several weeks. This was probably due to the oil and diethylamine being removed by a non-ionic solvent leaving the bromocresol green in its blue form.

Chromatography of Xanthene Dyes

RECENTLY, Lima and Pieroni[1] have directed attention to the heterogeneous character of the dye rose bengal, which, when labelled with iodine-131, is used in tests of hepatic function[2,3]. Applying the ethanol–ammonia solvent system of Ishida *et al.*[4], they claim resolution of this dye into four components, three coloured and one colourless.

In the course of an investigation of the phloxin/tartrazine method, described by Lendrum[5] for the staining of connective tissues, I have had occasion to examine chromatographically most of the xanthene dyes in common use, and feel that my results may be of interest in relation to the observations quoted above.

A slight modification of the solvent system of Ishida *et al.*[4] was found to be the most useful ; this consisted of 0·880 ammonia, ethanol and water in the proportion 5 : 10 : 85 (by volume). Paper chromatograms were run on Whatman No. 1 paper 20 × 40 cm. by the descending method of Consden *et al.*[6] with the modification that the dye was applied as a thin line at the starting point. Circular chromatograms by a variation[7] of the method of Rutter[8] were found to be convenient for the rapid comparison of different batches and gave good separations. R_F values tended to show some variation, and the values quoted below are the mean values of several results.

Commercial halogenated fluoresceins examined included eosin *Y* ([*R*]-tetrabromofluorescein), erythrosin *R* ([*R*]-di-iodofluorescein) and erythrosin *B* ([*R*]-tetraiodofluorescein). The first of these dyes showed two coloured components, R_F values 0·16 and 0·22 ; the second gave five components, R_F values 0·08, 0·15, 0·26, 0·49 and 0·64 ; the third dye gave two components with R_F values 0·08 and 0·15.

Studies made on the partial halogenation of fluorescein with bromine and iodine in aqueous alkali showed that even at the stage where only one molecular proportion of halogen had been added, the reaction mixture could be resolved chromatographically into five coloured components, the position of the absorption maxima of which decreased *pari passu* with increase of R_F value. The R_F values of these components were, after bromination: 0·16, 0·22, 0·33, 0·52 and 0·64; after iodination: 0·08, 0·15, 0·26, 0·49 and 0·64. The components with R_F 0·64 were identical and could not be distinguished on chromatographic or spectroscopic criteria from fluorescein. It would seem a reasonable assumption that the four other components in each case represent the mono-, di-, tri- and tetra-halogenated fluoresceins. Further halogenation of the initial mixture resulted in a gradual decrease in the proportion of components of high R_F value. The end-product in each case had two coloured components which appeared to be identical with those of commercial samples of eosin *Y* and erythrosin *B*, respectively.

Essentially similar results were obtained in experimental halogenation of [*P*]-tetrachlorofluorescein. The R_F values for the components were in this case: bromination: 0·40, 0 48, 0·59, 0·71 and 0·77 ([*P*]-tetrachlorofluorescein); iodination: 0·31, 0·42, 0·54, 0·71 and 0·77. A commercial sample of rose bengal (extra) had two coloured components with R_F values of 0 31 and 0·42; these were presumably the tri- and tetra-iodo[*R*]-tetrachloro[*P*]-fluoresceins. Six samples of commercial phloxin *B* (*C.I.* No. 778) were examined. These were generally more complex mixtures than the dyes mentioned above. Some of the fractions could be identified with the products of bromination of [*P*]-tetrachlorofluorescein and in one case there appeared to be admixture with iodinated fluoresceins. It is possible that the other components are derivatives of [*P*]-dichlorofluorescein, which is stated[9] to be the basis of phloxin (*C.I.* No. 774).

In addition to the multiplicity of coloured components in these dyes, an examination of the chromatograms in ultra-violet light revealed the presence of a number of colourless components which showed brilliant fluorescence. This was especially marked in the case of derivatives of [*P*]-halogenated fluorescein. In some of the samples of phloxin *B*, as many as four such components could be found.

In view of the statement by Stowe, Delprat and Weeks[10] that the liver only eliminates rose bengal when this latter is fully halogenated, a careful chromatographic examination would appear to be essential in this and similar applications of the xanthene dyes.

The work reported here was supported by a grant from the British Empire Cancer Campaign. I would like to thank Dr. C. H. G. Price for his valuable advice.

PHYSIOLOGY

Hormonal Control of Moulting in Amphibians

MOULTING in amphibians starts when a new stratum corneum of the epidermis is formed. When moulting is normal the old stratum corneum is loosened and the slough thus formed is finally shed. (In the literature on amphibians, 'moulting' is often used synonymously with 'sloughing', that is, to denote merely the shedding of the slough.)

It is well known that moulting is abnormal in hypophysectomized amphibians. This is especially conspicuous in toads and most urodeles where hypophysectomy prevents shedding of the slough, whereas formation of strata cornea continues; eventually a dark-brown, thick, cornified layer covers the skin.

In urodeles thyroidectomy inhibits sloughing as effectively as does hypophysectomy. Reversely, sloughing can be produced by injection of thyrotropic hormone into hypophysectomized animals or of thyroxin into hypophysectomized or thyroidectomized animals[1–3]. Sloughing was also caused by thyroxin in hypophysectomized *Bufo arenarum*, but was not inhibited by thyroidectomy[4]. Sloughing was not inhibited by thyroidectomy or treatment with thiourea or thiouracil in *B. regularis* (Ewer, D. W., personal communication), or by treatment with thiourea or thiocyanate in *B. bufo* (Rosenkilde, Per, personal communication).

During investigations on hypophysial function in the toad *B. bufo* we observed that injection of adrenocorticotrophic hormone could cause sloughing in hypophysectomized animals. It was therefore found of interest to compare the effects of thyroxin and adrenocorticosteroids on moulting after hypophysectomy in a urodele (*Amblystoma mexicanum* Cope) and in a toad (*B. bufo* (L)).

Normally, *A. mexicanum* does not metamorphose. The skin of the unmetamorphosed animals does not hyperkeratinize in response to hypophysectomy in contrast to the skin of metamorphosed animals[3]. Metamorphosis was therefore induced by injection of 50 μgm. thyroxin. The animals of both species weighed around 50 gm. In *Bufo* only pars distalis of the hypophysis was extirpated; in *Amblystoma* the neuro-intermediate lobe was generally removed together with the pars distalis, because the two parts are not easily separated in this species. The technique of operation in *Bufo* has been described previously[5]. A similar technique was used in *Amblystoma*. Injections were given subcutaneously of thyroxin (Roche) and "Decorton" (Organon, deoxycorticosterone acetate, D.C.A., dissolved in peanut oil). Control injections of peanut oil were made.

In hypophysectomized *Amblystoma*, 50 μgm. thyroxin caused sloughing 2–3 days after injection, whereas in hypophysectomized *Bufo* 50 μgm. or 100 μgm. thyroxin had no effect (Table 1). In contrast, deoxycorticosterone acetate caused sloughing in *Bufo*, but not in *Amblystoma*. Both in *Amblystoma* and *Bufo* 0·5 mgm. deoxycorticosterone acetate was given twice a week for several weeks. The slough was not shed in *Bufo* after every injection, but when sloughing occurred it was always within 24 hr. after the injection. In seven toads 33 moults were produced; one toad died a week after hypophysectomy without sloughing. Control injections of oil had no effect on the skin. Mostly the sloughs were eaten

Table 1. EFFECT OF THYROXIN AND DEOXYCORTICOSTERONE ACETATE ON SHEDDING OF CORNIFIED LAYER OF EPIDERMIS IN HYPOPHYSECTOMIZED *Bufo bufo* AND *Amblystoma mexicanum*

Treatment	Species	Dose (mgm.)	No. of animals in which cornified layer was Shed	Not shed
Thyroxin	*B. bufo*	0.05	0	8
		0.1	0	6
	A. mexicanum	0.05	5	0
Deoxycorticosterone acetate	*B. bufo*	0.5	7	1
	A. mexicanum	0.5	0	5

as they are during normal moulting. However, the injections did not restore the normal moulting rhythm. New strata cornea were produced two or more times a week as in untreated hypophysectomized toads, whereas the normal controls moulted only about once a week.

It is probably not justified to conclude from the present experiments that sloughing is dependent exclusively on the thyroids in *Amblystoma* and on the adrenals in *Bufo*. Both glands may play a part in sloughing as well as other phases of moulting in both *Amblystoma* and *Bufo*, though seemingly to varying degrees.

In the literature it is more often tacitly understood than directly expressed that the moulting cycles in amphibians are maintained and controlled by rhythmic activity of the thyroids. Adams *et al.*[6], however, clearly state that they find it likely that the moulting rhythm in *Triturus* "is dependent at least in part on an endocrine (pituitary–thyroid) balance". Scharrer[7] considers the moulting rhythm in *Bufo* to be regulated by a special centre in the central nervous system, the centre acting via the hypophysis and the thyroids.

However, the following observations do not support the assumption that the single moult is normally initiated by increased activity of the thyroids—or other endocrine glands.

(1) In metamorphosed *Amblystoma* the transplanted hypophysis is able to maintain the thyroid activity at a level that permitted the normal moulting cycles to continue. The glands were transplanted under the palate mucosa and could therefore scarcely be rhythmically stimulated by any moulting centre[8].

(2) Injection of thyroxin into normal *Amblystoma* or *Bufo* did not immediately cause sloughing or loosening of the stratum corneum, but the moulting frequency was raised during the week or weeks following a single injection. This was especially pronounced in *Amblystoma*, which moulted almost daily for about a week—or some five times faster than normally—after a single injection of 50 μgm. thyroxin (Table 2). After about four moults in rapid succession sloughing stopped completely for up to three weeks. During this period the epidermis became covered by a thick cornified layer which was finally shed spontaneously; and an almost normal moulting rhythm was resumed. The observations are naturally explained by assuming that the high level of thyroxin in the blood immediately after the injection enhanced the rate of moulting, but at the same time inhibited the activity of the thyroids for several days so that the level of endogenous thyroid hormone did not permit sloughing. Shedding of the sloughs continued as long as sufficient exogenous thyroxin remained in the blood, and after this period did not start until the animal's own thyroids functioned again. In the hypophysectomized *Amblystoma* the single injection of thyroxin also initiated a burst of moults.

Table 2. NUMBER OF MOULTS PER WEEK IN FIVE *Amblystoma mexicanum*

	Before	After injection of 50 μgm. thyroxin (weeks)						
		1	2	3	4	5	6	7
Normal animals	6*	18	2	0	3	7	8	8
Hypophysectomized animals	0	21	0	0				

*Average of the seven weeks that preceded the injection.

(3) Finally, it should be stressed that hypophysectomy inhibits the shedding, but not the formation of the slough; new strata cornea are still being formed and even faster than normally.

Thus normal moulting depends upon or may be influenced by the function of the thyroids, adrenal cortex and perhaps other endocrine glands as well[9]. The frequency of moulting is determined by the level of activity of the thyroids and not by a rhythm of activity; the ability to moult rhythmically is apparently inherent in the skin.

Selective Biological Membrane Transport of Individual Amino-Acids

THE behaviour of amino-acids in high-tension (100–300 V./cm.) electrostatic fields has recently been investigated in this laboratory. A phenomenon (to be described shortly) was observed, and it led to a hypothesis which is summarized in the following.

Since the Donnan effect cannot explain the selectivity of membrane transport of molecules larger than mono- or di-atomic ions and the Michaelis theory[1] becomes more and more[2] justified, we think our observations have given us an explanation of many problems, among them, for example, why cells put into a concentrated solution of amino-acids take up only a determined amount of amino-acid and not more[3]. How can it be explained by the Donnan effect why cells do take up only specified amino-acids or other molecules, and why can one or the other be substituted by a completely different kind of molecule[4], etc.?

However, to-day we know more about the structure of some biologically important membranes. The electron microscope has shown that phospholipid molecules are arranged[5] in the anterior pituitary gland cell wall in a laminary way, 20 Å. apart from each other in triplets, making up a thickness of 75 Å. Halpern and Binaghi have shown a selective permeability of certain biological membranes[3] to carbonic acid, and a similarly selective activity of the human erythrocyte membrane towards uric acid has been demonstrated[6], and further that calcium ion has an important role in maintaining this selective permeability was shown by Maizels[7]. Putting together the findings of the above workers and several others as well as ours we came to the following conclusion.

An amino-acid—let us keep for the sake of simplicity to this example—which has been liberated from the food protein by digestive ferments finally acquires an electrostatic charge in the jejunum. The amino-acid will then approach the wall of the gut (and it must not get nearer to it than 50 Å.[8]) at a point where there is a venous capillary or lymph duct on the other side. At these points the inside of the gut membrane will have a polarity and potential sufficiently great enough to attract the amino-acid, which bears an opposite polarity and has enough reserve energy[9] to alter its structure into another form—an elongated one most probably. This enables it to pass now the approximately 20-Å. wide opening on the membrane towards which it is pulled. As soon as the amino-acid reaches the other side of the membrane it will be pushed away since this side has the same polarity as the amino-acid, and will travel along by now, let us say, in the venous capillary, returning to its original structure. Since the *p*H value of the blood will differ from that in the gut, the amino-acid receives a new charge and also, possibly, alters its polarity.

The electrostatic structure of the ribo-nucleus molecule in a given cell, at some distance from our amino-acid, will cause the production by that cell of a certain quadruple peptide. When three given amino-acids in this cell are already linked together, a certain pattern of polarity and electrostatic charge will be set up, which will affect the cell membrane either as a whole or only a part of it. It is necessary for this hypothesis that this individual cell membrane should be some ten times more sensitive to changes in electrostatic charge than the gut membrane. This will enable the cell to discriminate between individual amino-acids. When the 'missing' amino-acid reaches the vicinity of the cell it will be attracted to it and will enter into it with the same type of changes as were described when it passed through the gut membrane, except that when it now reaches the cell interior, instead of moving around freely it will immediately combine with the already coupled group of amino-acids, thereby changing the electrostatic state of the cell again. The completed quadruple peptide will then be either incorporated structurally into the cell, or the polar and electrostatic changes will enable the peptide to pass through the cell membrane and get into the blood circulation, where it can be used up for any further macro-molecular building.

This selectivity of membrane transport for amino-acids has been demonstrated in this laboratory on a small-scale, simple model-experiment. Two amino-acids, histidine and aspartic acid, were dissolved in a buffer solution at a *p*H of 8·6 and kept at 38° C. with a constant slow stirring. Into it, five tubes were dipped, the lower end of each being covered by a 'Cellophane' membrane. The tubes contained the same buffer solution but the *p*H was varied in steps of 0·2 from 7·0 to 7·8. At the end of 5 hr. it was found that all aspartic acid was in the tube of *p*H 7·0 and all the histidine in the tube of *p*H 7·2. No amino-acid was detected in any of the other three tubes, or in the original buffer solution.

Further work on this problem is being carried out with the close co-operation of the Marconi Instruments Co., Ltd., on a larger and more critical scale. It is hoped that this further stage of the model-experiment will throw more light on the problem of specific membrane transport.

Induction of a Vascular Permeability Factor by the Interaction of Guinea Pig Tissue Debris with Serum

THE sera of the guinea pig[1,2], rat[3], rabbit[3] and man[4] contain the inactive precursor (*pro-PF*) of a globulin permeability factor (*PF*) activable by dilution in saline (*PF/Dil*) or by chemical fractionation. The *in vivo* mechanism of activation is unknown; but an obvious hypothesis—that activation in injury is induced by contact of the *pro-PF* with damaged tissue—was investigated by testing the effect on guinea pig serum of debris from homogenates of guinea pig tissues.

Guinea pig serum was harvested from defibrinated blood[5] and stored at 2° C. The excised tissues were freed of adherent connective tissue bearing blood vessels and disrupted[6] in sterile 0·85 per cent saline, using a loosely fitting homogenizer of the Potter type. The homogenate was centrifuged at 3,000*g* for 20 min. and the supernatant decanted. The residual tissue debris, twice washed in 20 vol. saline, was suspended in saline, such that 1 gm. wet tissue yielded 1·5 ml. tissue debris suspension. Dried tissue debris was obtained by adding the suspension to 10 vol. acetone, removing the debris 10 min. later by filtration and drying it in a stream of air. Permeability-increasing activity of the preparations was estimated in terms of the diameter of the area of exudation of circulating pontamine blue induced at the site of intracutaneous injection in depilated guinea pigs[7].

The ready and progressive activation of *pro-PF* to *PF/Dil* by dilution of normal serum in saline depends on the age and temperature of the dilutions[1]. In preparations held 90 min. at room temperature, maximum permeability-increasing activity occurs in 1/150 serum, but at this time low dilutions of serum, 1/1–1/15, have no substantial activity because activated *PF* has been antagonized by a low-potency, slowly acting inhibitor (*IPF*) present therein. A second factor (*PF/Age*)[1] matures in serum kept for one or more days. *PF/Dil* is characterized by its insusceptibility to the antihistamine, mepyramine maleate, and its high susceptibility to trypsin inhibitors like that from soya bean (*SBTI*); *PF/Age* is not antagonized by *IPF*, *SBTI* or mepyramine.

Tissue debris suspensions of lung, liver, heart, skin, brain and skeletal muscle each were mixed with 2·5 vol. serum and after 15 min. the debris was removed by centrifugation. All except skeletal muscle induced permeability-increasing activity in the treated serum (Table 1). The most active, brain debris, was investi-

Table 1. PERMEABILITY-INCREASING ACTIVITY OF SERUM TREATED WITH HOMOGENATES OF VARIOUS TISSUES

Tissue homogenate	Mean diameter (mm.) of area of increased permeability induced by: Saline extract	Treated serum (1/3)
Lung	2 9	5·5
Liver	2·6	5·6
Heart	2·8	6·1
Skin	2 9	6 6
Brain	3 5	7·8
Skeletal muscle	3·9	3 9
None	—	4·2

gated. Mixed with normal serum, within 5 min. it led to the appearance of a new permeability factor in the 1/1–1/15 dilutions. The amount of factor produced was proportional to the amount of brain debris added; and 1 hr. exposure to debris was no more effective than 5 min. The new factor produced by the reaction of debris with serum differed from *PF/Dil* in being insusceptible to *SBTI*, only slightly susceptible to serum fractions containing *IPF*, but highly susceptible to mepyramine. In fact, the addition of mepyramine to dilutions of treated serum restored the pattern of activity to that of untreated serum. These results also distinguish the new permeability factor from *PF/Age*.

Saline extracts of dried brain debris and the supernatant fluid from brain homogenate also contain a permeability factor with the same susceptibility to inhibitors. Moreover, all three preparations—fresh debris mixed with serum, the supernatant from fresh debris and a saline extract of dried debris—induced a slow contractor response in atropinized guinea pig ileum *in vitro*, which was not suppressed by mepyramine; and on injection into the rat peritoneal cavity[8], all three readily released histamine (Table 2). That is, the new factor appears to be a histamine-liberator. Prepared from saline extracts of dried debris, it is stable for 10 min. at 60°, 80° or 100° C. It does not appear to be associated with a protease system (for example, plasmin) because *SBTI*, 333 μgm./ml., also fails to inhibit its appearance in mixtures of serum and debris.

Table 2. HISTAMINE RELEASED IN THE RAT BY THE INTRAPERITONEAL INJECTION OF DEBRIS FACTOR AND OTHER PREPARATIONS

Substance injected	Histamine yield Exudate (μgm./ml.)	Body-weight (μgm./100 gm.)
Compound 48/80 (ref. 11) 15 μgm./ml.	0 20	1 03
Debris in 1/3 serum	0 24	0·94
Untreated 1/3 serum	0 00	0·00
Supernatant of brain homogenate*	0·15	1·00
Dried debris	0·13	0 42
Locke's solution	0·03	0·14

* Prepared in Locke's solution.

It is suggested that many tissues normally contain a bound histamine-liberator, which is released on mechanical disruption, after treatment with acetone or by the action of serum on damaged tissue. Moreover, the results provide a model for a tissue mechanism of histamine liberation—serum releasing histamine directly from injured tissue, or activating the factor, which in turn liberates histamine. *In vitro* the reactions are rapid; release of the factor by serum is complete in 5 min., the shortest period tested; and the released factor, injected intracutaneously, increases permeability in ½ min.

The new factor may mediate the immediate permeability response of tissues to injury[9]. However, it is not possible at this stage to evaluate the relation of this system to the superficially similar one described by Spector[10] in the serum and pulmonary mitochondria of the rat, and ascribed by him to an activation of serum *pro-PF* by mitochondria.

Ataxia in Hens poisoned by Tri*para*ethylphenyl Phosphate

IT has been known for almost 30 years that the administration of tri*ortho*cresyl phosphate and certain other organo-phosphorus compounds produces demyelination in the central and peripheral nervous system of some species. Earl and Thompson[1] suggested that the lesions might be associated with the anticholinesterase activity of the drugs *in vivo*, but Davison[2] later demonstrated that some other organo-phosphorus compounds, which were equally effective as inhibitors of cholinesterase, did not cause demyelination or ataxia. More recently another arylphosphate, tri*para*ethylphenyl phosphate, has been synthesized, which causes ataxia in hens[3], but, unlike the other demyelinating agents of this class, it does not possess demonstrable anticholinesterase activity (Aldridge, W. N., and Barnes, J. M., personal communication). The results with this material appear to provide conclusive evidence that the organo-phosphorus compounds do not produce demyelination by virtue of their anticholinesterase effects.

However, it may be wrong to assume that the toxic action of all the demyelinating drugs in this group is exactly the same. In this laboratory, it has been observed that the clinical picture produced in hens dosed with tri*para*ethylphenyl phosphate differs very strikingly from that seen with tri*ortho*cresyl phosphate poisoning. In hens poisoned by tri*ortho*cresyl phosphate, ataxia is associated with very marked flexion of the joints of the leg and with curling of the toes. In contrast to this, extensor tone is greatly increased in the hens dosed with tri*para*ethylphenyl phosphate; these stand on tiptoe and walk with exaggerated extension of the legs. In the late stages, when their legs are unable to support their weight, the birds sit with their legs extended rather than flexed. Another difference is in the time course of the condition; in tri*ortho*cresyl phosphate poisoning changes in gait are never seen before the seventh day after dosing, but once symptoms appear the condition progresses rapidly and many birds became moribund during the third or fourth week. Only those birds with relatively mild symptoms survive, and recovery is extremely slow; for example, one bird was still ataxic 27 weeks after dosing. On the other hand, symptoms appear as early as the fourth day after tri*para*ethylphenyl phosphate has been given but they increase more slowly and less steadily than in tri*ortho*cresyl phosphate poisoning. While some of the birds with severe disabilities have died, others have shown obvious improvement from the fourth to fifth week and in some less-affected hens recovery has been almost complete 7 weeks after dosing.

Although no claim is made on the basis of this work that tri*para*ethylphenyl and tri*ortho*cresyl phosphates produce their effects by a different biochemical pathway, the findings suggest that such a possibility should be considered. In view of this it seems important that workers in this field should describe their clinical observations more precisely than hitherto. It may be wrong to classify all organo-phosphorus-produced disabilities as 'Ginger Jake paralysis'.

Glucagon : a Protein Catabolic Hormone in the Isolated Perfused Rat Liver

WE have reported that the isolated perfused rat liver from a fasted animal produces urea in linear fashion[1], at the expense of both liver and plasma proteins. Urea production occurs, and the blood amino-acid level is maintained in the absence of added extraneous amino-acids. When a free amino-acid supplement is added, urea production is greatly enhanced. The addition of glucose or fructose supplements is associated with a nitrogen-sparing effect manifest as a diminished production of urea. This nitrogen-sparing effect is seen in either the presence or absence of added amino-acids.

The production of urea by the isolated perfused liver may be regarded as a measure of the continuing or endogenous protein catabolism, and the isolated perfused liver affords a means of studying protein catabolism and the effects of various agents upon it.

This communication reports a remarkable effect of the hormone glucagon (generously supplied by the Eli Lilly Co.) in enhancing protein catabolism in the isolated perfused liver.

In typical experiments a 6-hr. liver perfusion is started and continued for a base-line period of 1½–2 hr. During this time, Ringer's solution is continuously infused. After this the continuous infusion is changed to one of Ringer's solution containing glucagon in such concentration that as little as 1 μgm. of glucagon is infused per hour.

Blood samples are removed at regular intervals, analysed for urea by Conway's method and for glucose by Nelson's method. The total amount of urea produced during each interval is computed after appropriate correction for the amount of urea removed by the sampling procedure itself.

Not only is prompt glycogenolysis produced by as little as 1 μgm. of glucagon per hour, but also, as Fig. 1 shows, the rate of urea production is greatly increased. Almost complete glycogenolysis occurs in the face of blood glucose-levels known to promote glycogen deposition[2] and also to spare protein[1].

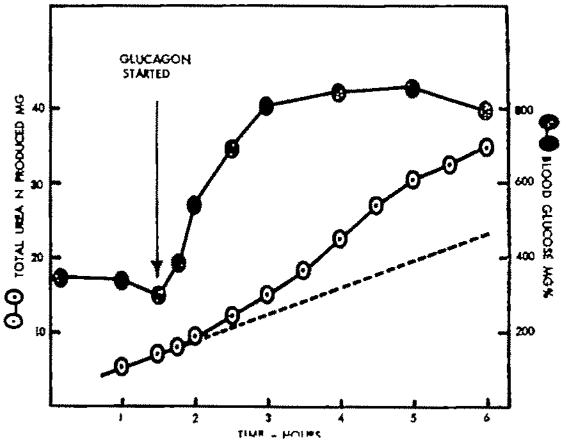

Fig. 1. Liver donor fed stock laboratory diet. Blood donors fasted 18 hr. before being bled to provide a total of 63 ml. of whole blood diluted with 35 mgm. heparin and Ringer's solution to 79 ml. at start of perfusion. Perfused liver weight, 14 gm.; glycogen content at 1½ hr. 2·64 gm. per cent, and at 6 hr. 0·11 gm. per cent. Over an interval of 1½–6 hr. glucagon was infused at the rate of 1 μgm. per hr. in 3 ml. of Ringer's solution

It is of some interest that the hormone hydrocortisone in the form of the soluble succinate given by continuous infusion in amounts up to 2 mgm. per hour produces no change in the output of urea by livers from either normal or adrenalectomized rats. Only when glucagon is infused into livers from the latter along with hydrocortisone is a maximal increase in protein catabolism elicited. Given alone, in perfusion of the adrenalectomized rat liver, glucagon causes a small but definite increase in protein catabolism.

The glycogenolytic effect of glucagon at 1 μgm. per hour on the liver is not altered by prior and continuous administration of insulin in amounts known to be sufficient to enhance glucose uptake and lipogenesis[3]. However, the protein catabolic effect of 1 μgm. per hour is abolished by the insulin.

Although relatively massive doses of glucagon given parenterally to intact rats have been associated with enhanced urinary nitrogen excretion[4], the site of action and the mechanism of the response have not been defined. Our experiments implicate the liver directly and point to glucagon as being a protein catabolic hormone *par excellence*, with adrenal corticoid hormone exerting a permissive action on this effect.

This work was performed under contract with the United States Atomic Energy Commission at the University of Rochester Atomic Energy Project, Rochester, New York, and was supported in part by research grants from the Jane Coffin Childs Memorial Fund for Medical Research and from the Medical Research and Development Board, Office of the Surgeon General Department of the Army.

Effects of Reserpine, Serotonin and Vasopressin on the Survival of Cold-Stressed Rats

In the preparatory stages of a projected study of the hypothalamic control of release of adrenocorticotrophic hormone, large doses of reserpine, serotonin creatinine sulphate, and commercial vasopressin were administered to rats which were then subjected to cold stress. Preliminary findings are reported here in view of the widespread interest in the drugs from the point of view of pituitary-adrenal physiology[1] and in view of the current extensive use of reserpine in medicine.

Intact male rats of the Harvard strain weighing 95–105 gm. were selected. All substances were administered subcutaneously, and cold-exposed controls received volumes of vehicle equal to those injected into the test animals. The rats were placed in individual screen-bottomed cages without food or water in a cold room at 3° ± 1° C. either immediately following the injection, or in some cases 18 hr. after injection. To minimize variations due to cyclic changes in physiological activity the animals were placed in the cold room at approximately the same time (1200 midnight ± ½ hr.) except for one stressed control group which was exposed to cold starting at 11 a.m. Treated controls were kept at room temperature under otherwise similar conditions. For the sake of comparison a group of adrenalectomized animals (1 week after surgery) in the same weight range was similarly stressed. The results are summarized in Table 1.

It is evident that large doses of reserpine, serotonin creatinine sulphate, and commercial vasopressin effectively lower the ability of intact rats to withstand cold stress, although on the basis of the experiments described here it is not possible to offer any demonstrable explanation for the mechanisms involved; however, the similarity in the survival-times of serotonin- and vasopressin-treated rats and the survival times of adrenalectomized animals suggests that treatment with these two drugs—both of which are known to exert some action on the pituitary-adrenal system[1]—results in temporary functional adrenalectomy.

Table 1. EFFECTS OF RESERPINE, SEROTONIN CREATININE SULPHATE AND VASOPRESSIN ON THE SURVIVAL-TIMES OF COLD-STRESSED RATS

Treatment	Survival time*	No. of animals
1 Intact controls, exposed at 1200 midnight	19·25 ± 1·8 hr.	20
2 Intact controls, exposed at 11 a.m.	9 56 ± 1·0 hr.	9
3 Adrenalectomized, untreated animals	2·98 ± 0 8 hr	9
4 2 mgm. serotonin creatinine sulphate, stressed immediately after injection	< 4 hr.	10
5 1 mgm. serotonin creatine sulphate, stressed immediately after injection	< 4 hr.	10
6 1 mgm. serotonin creatinine sulphate, stressed immediately after injection	3 57 ± 0·6 hr.	7
7 2 mgm, serotonin creatinine sulphate, stressed 18 hr. after injection	killed after 15 hr.	8
8 1 mgm. serotonin creatinine sulphate, stressed 18 hr. after injection	killed after 15 hr.	8
9 1 mgm. reserpine, stressed immediately after injection	9·5 ± 0·6 hr.	18
10 1 mgm. reserpine, stressed 18 hr. after injection	10·5 ± 0 7 hr.	10
11 3 units vasopressin, stressed immediately after injection	2·08 ± 0·15 hr.	6
12 2 units vasopressin, stressed immediately after injection	3·06 ± 0·53 hr.	9
13 3 units vasopressin, stressed 18 hr. after injection	killed after 15 hr.	6
14 2 units vasopressin, stressed 18 hr. after injection	killed after 15 hr.	6

All treated controls kept at room temperature survived for 24 hr. and were killed at that time.

* Mean ± standard error of the mean.

Reserpine clearly differs from the other substances tested in that its effects are still evident 18 hr. after injection, although most of the drug is known to have been metabolized by then[2]. The survival times of intact controls exposed to cold stress at different times of the day appear to reflect the daily cyclic changes in adrenal activity[3].

Potency of Parenteral Vitamin A

Vitamin A is widely employed in clinical practice and is also used extensively as a teratogenic agent for the production and study of fœtal abnormalities in laboratory animals[1].

Up to the present the customary procedure in experimental work has been for the vitamin to be dissolved in oil and administered orally. This method has a number of disadvantages. In order to ensure that the animal receives the required dose, it is necessary to put the dissolved vitamin directly into the stomach by the somewhat laborious procedure of gastric intubation. Once in the alimentary tract, defects of absorption may lead to the loss of a substantial amount of the vitamin in the fæces. Such defective absorption may be due to the presence of gastric or intestinal inflammatory conditions, to a deficiency in the secretion of bile which leads to a failure in the breakdown of the fat in which the vitamin is dissolved, or to the nature of the oil itself[2]. Some of these factors may also militate against absorption of the vitamin when employed for therapeutic purposes in man.

Subcutaneous or intramuscular injection has many advantages in experimental work from the point of view of convenience and the more precise measurement of dosage, but the results of the injection of oily solutions of vitamin A have been disappointing. Brown and Sturtevant[3] found that during a 28-day test period little if any benefit resulted from injection and concluded that vitamin A in oil injected subcutaneously or intramuscularly was utilized to a very small extent if at all. Their conclusions are borne out by the results of experiments which we have carried out in rats. The subcutaneous injection into rats of 60,000 I.U. vitamin A dissolved in arachis oil daily from the eighth to the thirteenth day inclusive of pregnancy did not produce any cleft palates in the young, whereas the same quantities given by gastric intubation over the same period of time resulted in 29·7 per cent of cleft palates in the young[4].

Recently we have had the opportunity of studying the teratogenic effects of the subcutaneous injection of vitamin A stabilized in 'Tween 80'. Female rats of the Wistar strain were used. After mating with normal male rats, pregnancy was determined by the presence of spermatozoa in the vagina. The pregnant females received 60,000 I.U. vitamin A (suspended in 'Tween 80') daily by subcutaneous injection on the twelfth, thirteenth and fourteenth days of pregnancy.

The rats were killed on the twentieth day of pregnancy and the fœtuses removed from the uteri for examination. The results of the two pilot experiments in relation to malformations of the palate are shown in Table 1. In addition to the palatal deficiencies many of the young showed other skeletal malformations involving mainly reduction of the digits and syndactly.

Table 1 INCIDENCE OF CLEFT PALATE FOLLOWING PARENTERAL VITAMIN A

Group	No. of dams	Total No. of young	No of young with cleft palates	Percentage of young with cleft palates
1	8	68	49	72·0
2	7	54	49	90·7

The percentage incidence, in the fœtuses, of cleft palates produced by the subcutaneous injection of vitamin A compares closely with that of 92 per cent observed by Giroud and Martinet[5] when female rats were given 60,000 I.U. vitamin A, in oily solution, by mouth on the eleventh, twelfth and thirteenth days of pregnancy. The disparity in the percentage incidence of the malformation in our two groups of animals is probably due to the small numbers used in these pilot experiments, although some other unknown factor may be involved.

These experiments indicate that vitamin A suspended in 'Tween 80' is potent as a teratogen when injected subcutaneously. From the experimental point of view, the advantages of this route of administration over the oral are obvious. It may also be useful, at times, to be able to employ a parenteral route for therapeutic purposes.

This work has been supported by a grant from the Medical Research Council, which is gratefully acknowledged. We wish to thank Messrs. Vitamins, Ltd., for the preparation and gift of the vitamin solution.

The Nuclear Membrane as a Barrier to the Free Diffusion of Proteins

A RECENT investigation of the osmotic properties of the nucleus in intact frog oocytes has indicated that the nuclear membrane of these cells is not freely permeable to large molecules (mol. wt. 40,000 or greater)[1]. The present investigation was carried out in order to determine whether or not similar results could be obtained for oocytes of an unrelated species.

Immature oocytes of the *Cecropia* moth (family, Saturniidae), in which yolk formation was just beginning and in which the nucleus was clearly visible, provided a suitable material for this purpose. The ovarioles were removed from animals that had completed one-third of the pupal-adult moult, and placed in a hanging drop of *Cecropia* pupal hæmolymph in a moist chamber. A 0·4 per cent solution of fluorescein-labelled rabbit γ-globulin (fraction II) in nine parts 0·151 *M* potassium chloride (in a sodium chloride solution which is isotonic with this concentration of potassium chloride, *Cecropia* oocytes will neither swell nor shrink: Telfer, W. H., personal communication) and one part 0·01 *M* phosphate buffer was then micro-injected into the cytoplasm of suitable oocytes. The *p*H of the above solution was 7·4; a value selected after injections of phenol red into the oocytes indicated a cytoplasmic *p*H of 7·0 or higher. The protein solution was injected near the nucleus, and care was taken to avoid contact between the micropipette and the nuclear membrane. No changes in the appearance of the cells were observed as a result of micro-injection. 10 min. after being injected, the oocytes were removed from the moist chamber and fixed for 20 min.–2 hr. in three parts 95 per cent alcohol and one part glacial acetic acid. After paraffin embedding, the cells were sectioned at 7 or 8μ. The paraffin was removed from the slides with xylene and the sections were mounted in Schillebar's oil (Grade *A*).

When the slides were observed with the fluorescence microscope, the fluorescence was found to be distributed throughout the cytoplasm. There was, however, no sign of fluorescence in the nucleus (Fig. 1). The results have been interpreted as meaning that the nuclear membrane of *Cecropia* oocyte acts as a barrier to the free diffusion of γ-globulin (mol. wt., approx. 165,000). The main criticism of this interpretation is that, following injection into the cytoplasm, the protein could have been removed from solution either by precipitation or by binding to certain cytoplasmic constituents. However, the fact that the fluorescence was widely distributed through the cytoplasm within 10 min. after the injection indicates that the mobility of the fluorescein-labelled

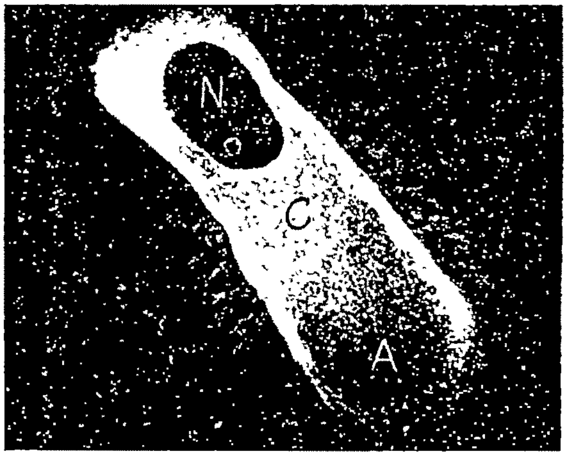

Fig. 1. A section through an injected oocyte showing the absence of fluorescein in the nucleus (*N*). Under the fluorescence microscope the nucleus appeared blue and the entire cytoplasm (*C*) was yellow. Due to a high concentration of granules, the fluorescence in area (*A*) did not show up with black-and-white photography

γ-globulin was sufficient for it to pass through the nuclear membrane if the latter were not impermeable.

It should be emphasized that the rather short 10-min. interval between injection and fixation was chosen for the specific purpose of determining whether the nuclear membrane can act as a barrier to the free diffusion of molecules having a large molecular weight. The inability of a protein to penetrate the nuclear membrane in short-term experiments does not necessarily rule out the possibility that proteins can actually pass into the nucleus. It is not inconceivable, as has been suggested by Stern and Mirsky[2], that an energy-requiring transport mechanism exists whereby molecules which cannot freely penetrate the nuclear membrane can enter the nucleus.

This investigation was supported by funds from a Rockefeller grant to the Zoological Laboratory. We wish to thank Dr. William H. Telfer for supplying the animals and also for his advice and encouragement, and Dr. John Marshall for supplying the fluorescein-labelled γ-globulin and for the use of his fluorescence microscope.

Reaction of Hibernators to Various Low Temperatures of the Environment

IN order to establish the conditions in which hibernators do not maintain their constant body temperature and enter hibernation in summer, the following experiments were made with European hamsters (*Cricetus cricetus* L.) in July and September 1959. Animals were exposed to various low temperatures and their oxygen consumption and rectal temperature recorded for 4 hr. Examples of the results of these experiments are given in Figs. 1 and 2, and mean values of the oxygen consumption in Table 1.

It can be seen that in the experimental temperature − 8° C. the oxygen consumption of the hamsters rose very steeply at the beginning of the experiment to a high level which was maintained throughout the experimental period. Rectal temperature remained constant at the original value about 38° C. The animals behaved like true homoiotherms in these conditions.

In the experimental temperature + 10° C. the course of the changes in metabolism and rectal temperature was quite different. The initial rise of the oxygen consumption was slow and a maximum was not reached until the animals were cooled to some degree. Hereafter the oxygen consumption decreased slowly, but distinctly in a wave-like manner; in connexion with it the rectal temperature fell similarly, the decrease amounting in the mean to 5·2° C. within 4 hr.

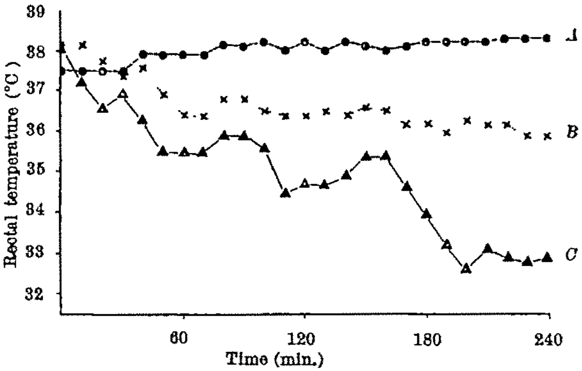

Fig. 1. Typical course of the changes of the rectal temperature in the European hamster in the experimental temperature −8° C. (*A*), + 2° C. (*B*) and + 10° C. (*C*)

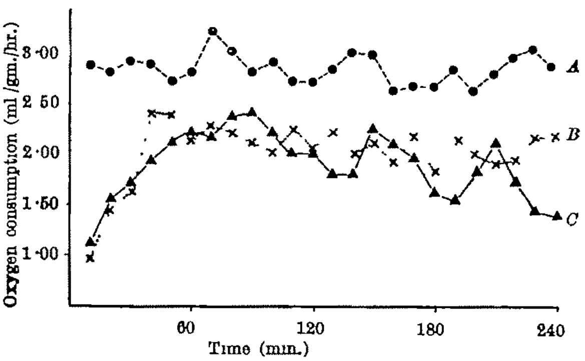

Fig. 2. Typical course of the changes of the oxygen consumption in the European hamster in the experimental temperature − 8° C. (*A*), + 2° C. (*B*) and + 10° C. (*C*)

In the experimental temperature + 2° C. reaction was intermediate between the two cases described: the oxygen consumption rose slowly, though more rapidly than in + 10° C., to a level which was lower than in − 8° C. and remained constant in the further course of the experiment. The rectal temperature fell rather rapidly during the first hour; later its fall was much slower.

The relative instability of the body temperature of hibernators even in periods of activity is well known[1-3]; it may, therefore, be questioned whether the fall of the rectal temperature observed in the experimental temperature + 10° C. after 4 hr. can be taken as evidence of a certain optimum temperature in which hibernation is induced. To obtain further evidence, animals were kept at a low temperature overnight (15 hr.) and their rectal temperature determined at the end of this period. The hamsters tolerated the temperature − 8° C. without any harm, their body temperature remained constant (38·2 ±

Table 1. MEAN VALUES OF OXYGEN CONSUMPTION IN THE EUROPEAN HAMSTER DURING EXPOSURE TO VARIOUS LOW TEMPERATURES OF THE ENVIRONMENT (SIX ANIMALS IN ONE GROUP)

Body-weight (gm.)	Experimental temperature (° C)	Oxygen consumption ml./gm./hr. First hr.	Second hr.	Third hr.	Fourth hr.
295–315	− 8	2·92 ± 0·18	2·90 ± 0·22	2·81 ± 0·29	2·83 ± 0·21
285–315	+ 2	1·80 ± 0·25	2·12 ± 0·14	2·04 ± 0·11	2·03 ± 0·17
290–320	+ 10	1·75 ± 0·18	2·13 ± 0·25	1·83 ± 0·17	1·62 ± 0·09

0·3° C. before, 37·6 ± 0·6° C. at the end of the exposure in six animals) and were normally reactive after 15 hr. In the environmental temperature + 10° C. their rectal temperature fell in the mean to 22·6 ± 3·2° C. (six animals), their mobility was considerably restricted and the hind parts of the body were partly torpid. The animals reacted only weakly to strong sound stimuli; sometimes they gave out throat sounds similar to those produced at the time of arousal from hibernation.

Preliminary experiments with the hedgehog (*Erinaceus europaeus* L.) gave results very similar to those obtained with the hamster.

Our results are analogous to the findings of Deane and Lyman[4] in the golden hamster and show that in hibernators exposed to a high stress a thermoregulatory apparatus of an effectivity comparable to that of non-hibernating mammals can be set in function. The decreased reflex control of warm production[5] appears to manifest itself only within those limits of the environmental temperature which may be taken as a component of the complex of the permissive environmental factors[6].

Although the lethargic state in hibernators has been sometimes experimentally produced in summer[7], cases have not yet been described in which the animals show signs of transition to the lethargic state after such a short exposure to low temperature. The facts described do not as yet exclude the necessity of a specific state of preparation for inducing the hibernation. They favour, however, the view that environmental conditions have the greatest importance.

Physiological Mechanisms concerned in the Maintenance of Lactation in the Goat and Sheep

THE anterior-pituitary galactopoietic hormones have been found to be essential for the maintenance of lactation in all species so far studied[1], and it is generally believed that the continued secretion of the galactopoietic complex is entirely dependent on nervous stimuli arising from the mammary gland[2].

Recently, some amplifications of Selye's theory have been put forward, and it has been suggested that the nerve stimuli may effect the release of prolactin and adrenocorticotrophic hormone from the anterior pituitary not directly but by way of the neurohypophysis through the intermediary of oxytocin[3] and perhaps vasopressin[4].

The experiments which gave rise to the neuroendocrine theory of the maintenance of milk secretion were carried out mainly on laboratory animals, and we thought it of interest to investigate whether the same conclusions are generally applicable to other species. For this purpose we have repeated many of these experiments on small ruminants (goats, sheep) and we have started by studying the effects of section of the afferent nerve pathways of the reflex. In a former experiment, the following procedure was carried out in goats and sheep during the first pregnancy.

Section of the lumbar nerves (first, second, third and fourth pairs), section of the perineal nerve with bilateral lumbar sympathectomy. In this experiment the operated animals, after parturition, gave considerable yields of milk.

Since this work was reported[5], we have carried out other experiments involving a greater degree of denervation of the mammary gland:

(1) Severance of all connexion between the mammary gland and the body except the inguinal blood vessels, with perivascular sympathectomy of inguinal blood vessels, followed by suturing of the gland back into position[6].

(2) Section of the spinal cord at *T*11 with bilateral sympathectomy and splanchnicectomy, also removal of the spinal cord between *T*11 and *L*5[7].

(3) Nerve section, resulting in insensitivity of the mammary gland and the adjacent areas, the experimental design and result of which are summarized in Tables 1 and 2. To eliminate any effects of possible regeneration of the perineal nerves, milk yields are given only for the first fifteen weeks of lactation although the yields were recorded over periods of 25–40 weeks. These results entirely confirm our previous experiments[5–7]. In a recent publication, Tverskoi[8] has similarly reported that cord section at *T*11 in the goat does not stop lactation.

Since, as the above findings show, goats and sheep can give substantial yields of milk in the absence of the milk-ejection reflex, it would seem that the milk-ejection reflex is not indispensable for lactation in these species.

The maintenance of the galactopoietic activity of the anterior pituitary in the absence both of the milk ejection reflex and of all mammary sensation may be explained in one of the two following ways. First, given currently accepted concepts of the maintenance of lactation, it may be supposed that some nerve fibres have remained intact, particularly in the deeper portions of the walls of the blood vessels. In this connexion the difficulty of achieving complete denervation is well known. This explanation, however, would only be valid if the fibres persisting in the walls of the inguinal vessels did not enter the main nerves supplying the mammary gland, but reached the spinal cord, at a level above *T*11 or the sympathetic chain above the thoracic ganglia through which the fibres of the splanchnic nerves pass. These assumptions, however, seem unlikely in view of anatomical studies of the nerve supply of the mammary gland[9]. Moreover, one would also have to assume that these hypothetical residual nerve fibres were concerned not with the transmission of stimuli inducing milk ejection or of painful tactile stimuli from the mammary gland, but were highly specialized and concerned entirely with the regulation of the secretory activity of the anterior pituitary. Our results make it difficult to believe that a small number of perivascular nerve fibres would suffice to transmit impulses sufficiently strong to regulate pituitary galactopoietic activity. Secondly, assuming that complete denervation of the udder has been achieved, it would appear to follow that secretion by the anterior pituitary of the galactopoietic complex is under humoral control.

Our experiments thus lead us to believe that the control of pituitary galactopoietic function may be

Table 1. MILK YIELDS OF EWES (FIRST LACTATION)

	Degree of denervation	No. of animals	Mean production per week for the first 15 weeks (ml.)	Total duration of lactation (weeks)

IV	Total of operated animals	15	4,128 ± 1,583	18·7
V	Normal animals	21	4,481 ± 1,820	19·4

* In groups I and II, the lateral femoro-cutaneous nerve may still provide some innervation.

Table 2. MILK YIELDS OF GOATS (FIRST LACTATION)

	Degree of denervation	No. of animals	Mean production per week for the first 15 weeks (ml.)	Total duration of lactation (weeks)
I	Lumbar nerves 1, 2, 3, 4, lumbar sympathectomy, perineal nerve, all bilateral section	11	3,528 ± 1,385	18
II	Thoracic nerves 12, 13, lumbar nerves 1, 2, 3, 4, perineal nerve, all bilateral section	1	5,238	42
III	Thoracic nerves 12, 13, lumbar nerves 1, 2, 3, 4, 5, lumbar sympathectomy, perineal nerve, all bilateral section	3	2,300	46
IV	Thoracic nerves 12, 13, lumbar nerves 1, 2, 3, 4, 5, perineal nerve, all bilateral section	2	3,652	42
V	Lumbar nerves 1, 2, 3, 4, 5, perineal nerve, all bilateral section	2	3,270	23
VI	Total of bilaterally operated animals	19	3,418 ± 1,390	27
VII	Lumbar nerves 1, 2, 3, 4, lumbar sympathectomy, perineal nerve, all unilateral section	7	3,682 ± 1,610	26
VIII	Normal animals	13	6,753 ± 3,300	25

In addition to bilateral denervations, we performed a sympathectomy on inguinal vessels and a section of the spermatic nerve at the lower inguinal ring.

comparable to that envisaged by Fortier[10] in respect of the secretion of adrenocorticotrophic hormone. On this view two main types of stimuli would condition the maintenance of lactation in the normal animal, the relative importance of these two systems varying with the species. First, nervous stimuli would act on the anterior pituitary according to the concepts of Selye[2] or of Benson and Folley[3], the immediate reaction of the organism to the peripheral stimulation being discharge of hormone. Secondly, there may be systemic stimuli associated with the physiological mechanisms of general adaptation of the organism to the demands of the lactating mammary gland for water, metabolites and hormones. These stimuli might act either directly on the anterior pituitary or at the level of the hypothalamus.

Urinary Œstrogens of the Dog

INVESTIGATIONS on naturally occurring œstrogens in the dog are few. So far as urinary œstrogens are concerned, controversial reports are given by authors using biological methods. Helm[1] and Kust[2] report negative findings for both non-pregnant and pregnant animals, while Lesbouyries and Berthelon[3], Finck[4], and Stiasny[5] found evidence for the presence of œstrogens in the urine of pregnant animals. Nilsson[6] reports positive values for non-pregnant bitches. In none of these investigations was the urine hydrolysed before assay.

So far as we know, no attempt has as yet been made towards characterization of the substances by chemical methods. In our laboratory the highly specific and sensitive method of Brown[7] for the chemical determination of œstrogens in human urine has been adopted for research in domestic animals[8]. This communication presents results indicating that by application of this method no significant amounts of œstrone, œstradiols and œstriol could be detected in the urine from male and from pregnant female dogs.

The material consisted of a batch of urine collected from three healthy male dogs, a batch from three healthy females during the last few days of gestation and a single specimen from another pregnant animal.

Two methods of hydrolysis were applied. In the recovery experiment on urines from males, hot acid hydrolysis was applied. A batch of 100 ml. urine was diluted to 200 ml. and boiled under reflux for 1 hr. using 15 vol. per cent hydrochloric acid. 20 μgm. quantities of free œstrogens were added to a parallel sample before acid hydrolysis. Pregnancy urine was submitted to enzyme hydrolysis, using a combined β-glucuronidase-phenolsulphatase preparation (1 ml. of the enzyme preparation contained 100,000 Fishman-units β-glucuronidase and 50,000–80,000 sulphatase-units). To 300 ml. urine was added hydrochloric acid to pH 5·0, and 60 ml. McIlvaine standard buffer (pH 5·0). After the addition of 1 ml. of the enzyme preparation and 100 mgm. of dihydrostreptomycin sulphate, the solution was incubated at 37° C. for 36 hr.

Quantitative determinations were then made on the different samples, using Brown's method[7] with slight modifications[8]. Values less than 1 μgm./l. of urine were considered insignificant.

Table 1. RECOVERY EXPERIMENT ON URINE FROM THREE MALE DOGS

Œstrone		Œstradiol-17-β		Œstriol	
μgm. added	μgm. recovered	μgm. added	μgm. recovered	μgm. added	μgm. recovered
0	0	0	0	0	0
20	8·7	20	7·9	20	11·8

The œstrogens were added *before* acid hydrolysis.

Table 2. ŒSTROGENS IN THE URINE OF PREGNANT BITCHES

Method of hydrolysis	Urine specimen	Œstrone	Œstradiol-17-β	Œstriol
Enzymic	Pooled from three bitches in late pregnancy	0	0	2·2
1 hr. reflux with 15 vol. per cent hydrochloric acid	Fresh from a single pregnant bitch	4·0	0	13·0
	Same urine after storage for 18 months at 4° C.	0	0	0

All values are uncorrected and represent μgm. per litre urine.

Results for male urine in Table 1 indicate that it is practically free from the œstrogens searched for. The recoveries lie well within the limits found by Diczfalusy and Westman[9] for human urine using a similar method.

As shown in Table 2, urine from pregnant bitches appears to contain only trace amounts of the œstrogens searched for. As enzyme hydrolysis, in our opinion, is considerably more efficient than acid hydrolysis, and is not known to cause destruction of liberated œstrogens, these observations can be considered valid. The presence of œstrogens other than those covered by the method applied in the present investigation can, of course, not be excluded. But generally, there seems to be agreement that the œstrogen-level in the urine of the dog is very low, regardless of physiological state. Our results tend to confirm this view.

PLANT PHYSIOLOGY

A Possible Relationship between Nucleic Acid Metabolism and the Initiation of Zygospores of *Rhizopus sexualis*

IT has been observed[1] in the homothallic fungus *Rhizopus sexualis* (Smith) Callen that the initiation and early stages of maturation of zygospores, which at 20–25° C. occur within a few days of inoculation, are completely inhibited at temperatures below 10° C. Later stages in the maturation of zygospores initiated at room temperature and afterwards transferred to low temperature are not inhibited; this suggests that a possible cause of the inhibition is a block in the synthesis of some compound or compounds essential for the early stages of zygospore production.

Some evidence is now available that the first stages of zygospore development are associated with a change in the nucleic acid metabolism of the organism. The nucleic acid content of cultures at different stages of development has been investigated by a procedure based on the perchloric acid extraction method of Ogur and Rosen[2], and it has been found that the level of total nucleic acids (either per culture or per unit dry weight of mycelium) reaches a maximum at the time of zygospore initiation and then falls. By a technique based on that of Korson[3] and used for fungi by Griffiths[4], the ribonucleic acid and the deoxyribonucleic acid of the cells can be differentially stained. This reveals that a rather high concentration of ribonucleic acid is maintained in the hyphal tips, up to the time of zygophore differentiation. Afterwards the level of ribonucleic acid falls rapidly; this fall appears to be accompanied by a rise in the deoxyribonucleic acid content, but later observations are made difficult by the pigmentation of the zygospore wall. In cultures in which zygospore formation is inhibited by low temperature the level of ribonucleic acid remains high. These results suggest that the deoxyribonucleic acid synthesis accompanying zygospore development may be at the expense of the ribonucleic acid of the mycelium, and that the inhibition noted at low temperature is due to a blockage of synthesis of deoxyribonucleic acid. A similar effect of low temperature upon the transformation of ribo- to deoxyribo-nucleic acid in higher plants has long been known[5].

Investigations of the effect of mature zygospores upon further zygospore initiation and development in the same culture resulted in the observation that a volatile compound is produced by mature cultures and is capable of stimulating zygospore production in younger cultures kept at room temperature and, in some instances, of initiating zygospore formation at low temperature. Mature cultures of related species of fungi also produce volatile substances with similar, although smaller, effects on cultures of *R. sexualis*. The activity is not due to carbon dioxide or ammonia, or to a lowering of oxygen tension. The active compound is apparently basic, since it can be removed from a gas stream by scrubbing with dilute hydrochloric acid and is not removed by potassium hydroxide. Attempts to identify the compound by means of a mass spectrometer have been inconclusive, but the fairly frequent occurrence of peaks of mass 15 and 16 is consistent with the possibility that the compound is methylamine. So far as is known, methylamine has not been reported as a metabolic product of *R. sexualis*, but it would not be surprising if it were formed in small amounts, especially in older cultures. When methylamine was supplied at the rate of 1 μgm. per hr. in the air stream passing over cultures at 9° C., there was evidence of a partial reversal of inhibition, in that irregular hyphal swellings similar to pseudophores were induced. In cultures in which zygospore initials were present before chilling, methylamine increased their rate of maturation. Other compounds, such as serine, choline and, to a lesser extent, formic acid, were effective when supplied with the culture medium in increasing zygospore production in cultures in which initiation had already begun. Methionine, betaine and glycine had no effect.

The evidence at present available suggests that the effect of low temperature on zygospore formation is to inhibit the interconversion of ribo- and deoxyribonucleic acid; this inhibition is at least partially reversed by chemicals which are closely associated with the metabolism of methyl and other monocarbon compounds in the cell[6]. In this connexion it is of interest to note that a major difference between ribo- and deoxyribo-nucleic acids lies in the presence of the pyrimidine uracil in ribonucleic acid and its replacement by thymine (5-methyl uracil) in deoxyribonucleic acid. Some of the chief metabolic sources of the methyl moiety of thymine incorporated in the deoxyribonucleic acid of young rats have been found to be serine and choline[7]. It is tempting to speculate that the non-availability of methylating agents needed for the synthesis of thymine and deoxyribonucleic acid may be the chief factor in the low-temperature inhibition of zygospore formation in *R. sexualis*. Critical experiments to test this hypothesis are in preparation, and it is hoped to publish a fuller account of this work when further results are available.

We wish to thank Dr. L. E. Hawker for introducing us to this problem, and for her help, interest and encouragement throughout the work. We are indebted to the Department of Scientific and Industrial Research for a studentship for one of us (P. M. H.).

Effect of Gibberellic Acid on Hypocotyl Growth of Lettuce Seedlings

Gibberellins are physiologically defined by their ability to induce shoot elongation in certain dwarf plants and they have been demonstrated in various plant extracts using dwarf maize plants[1] and dwarf peas[2–4] as assay material. Other assay material includes leaf sections of wheat seedlings[3] and sections of cucumber tendrils[5]. A convenient method employed by Murakami[6] involves the use of rice seedlings. Dwarf maize and pea plants, although very sensitive, are less convenient for assaying the several fractions obtained after paper chromatographic separation of plant extracts. An attempt was made to develop a simple means of bio-assay for this purpose.

The internode elongation shown by dark-grown pea seedlings can be reproduced in light-grown seedlings by gibberellic acid treatment. This has, in fact, been used as a bio-assay technique[7]. In seeds with an epigeal type of germination there is elongation of hypocotyl tissue as well as of internodes in the absence of light and it was decided to investigate the effect of gibberellic acid on hypocotyl growth in three species: *Lactuca sativa* (variety Grand Rapid), *Lepidium sativum*, *Hyoscyamus niger*. There have recently been brief reports[8,9] of the stimulatory effect of gibberellic acid on lettuce seedling growth.

Lettuce seeds were sown in the dark at about 25° C. After 2 days seedlings were selected with radicles of a similar length (6–8 mm.) and planted in 4 in. Petri dishes lined with filter paper moistened with 6 ml. of test solution. 10 seedlings were used per treatment. They were placed 15 cm. below a light source consisting of two daylight fluorescent tubes (5 ft., 80-watt), in which position the temperature was about 28° C. Hypocotyl length was recorded after 5 days, each hypocotyl being measured to the nearest mm. Gibberellic acid had a significant effect on hypocotyl growth at concentrations of 0·1 mgm./l. and above. Growth in 100 mgm./l. gibberellic acid was almost as great as growth of untreated seedlings in the dark. There was a linear relationship between hypocotyl elongation and the logarithm of gibberellic acid concentration. In the dark, hypocotyl growth was affected very little by gibberellic acid treatment. In subsequent experiments measurements were taken after 3 days and seeds were germinated in continuous light. This increased the light inhibition of hypocotyl growth but did not increase sensitivity to gibberellic acid.

Table 1. EFFECT OF GIBBERELLIC ACID ON HYPOCOTYL EXTENSION OF LETTUCE SEEDLINGS

Treatment, gibberellic acid in mgm./l.	Mean hypocotyl length ± *S.E.*	
	A	*B*
Untreated	6·0 ± 0·21	4·2 ± 0·13
0·01	6·0 ± 0·21	4·7 ± 0·21
0·1	9·7 ± 0·45	7·3 ± 0·33
1	13·1 ± 0·43	11·6 ± 0·54
10	17·3 ± 0·36	13·5 ± 0·40
100	19·1 ± 0·55	—
Untreated (dark)	20·3 ± 0·71	—
100 (dark)	21·8 ± 0·74	—

A, Lettuce seedlings germinated in dark prior to treatment. Measurements taken after 5 days. *B*, Lettuce seedlings germinated in light. Measurements taken after 3 days.

To investigate the specificity of the growth-response to gibberellins light-grown lettuce seedlings were also treated with the auxins, β-indoleacetic acid and 2-naphthoxyacetic acid. In neither case was there any positive growth response. Also sucrose had no effect on hypocotyl growth.

Hypocotyls of *Lepidium* and *Hyoscyamus* also showed positive growth responses to gibberellic acid but the effect was less marked than in lettuce.

The following procedure was employed when the lettuce hypocotyl test was used for assaying plant extracts following paper chromatographic separation. The extract was strip-loaded on a 10 cm. wide strip of Whatman No. 1 chromatography paper and developed in a descending fashion with a suitable solvent. The developed chromatogram was cut into ten transverse strips, each strip being cut into two and placed in a Petri dish on filter paper moistened with 6 ml. of water. Two-day-old lettuce seedlings were then planted on the chromatogram strips and hypocotyl growth measured after 3 days.

Using this technique it was possible to detect gibberellin-like activity in plant extracts, although the success of the bio-assay was mitigated by the presence of inhibitory substances in the extract, preventing true quantitative estimates from being made. It is intended to try out further chromatographic techniques which will effect more efficient separation of gibberellins from inhibitory substances.

The chief merit of this lettuce hypocotyl test lies in its simplicity. Seedlings are available for the bio-assay within 48 hr. of sowing and are small enough to be grown directly on the solution under test.

The work was supported by a grant from the Agricultural Research Council.

IMMUNOLOGY

Inhibition of the Inductive Phase of Antibody Formation by 6-Mercaptopurine examined by the Transfer of Isolated Cells

The inductive phase of antibody formation is a period that differs not only quantitatively but also qualitatively from the later productive phase[1]. This is seen from the effects of X-irradiation[2] and of cortisone[3] on antibody formation, and in particular from the results of tissue-culture experiments[4].

When inhibitors act on the whole organism, however, it is impossible to determine reliably whether they affect the inductive phase only, or also the productive phase. Antigen persists in the tissues for at least a week and during this time the mesenchymal stem cells normally proliferate. This gives rise to a situation in which the newly developing cells are stimulated by antigen (commencement of the inductive phase), while cells which were previously in contact with the antigen are in the productive phase. Since the outcome of the effect of inhibitors on the organism is not instantaneous, it is not always easy to decide during which phase the cells are affected. I therefore examined the effect of inhibitors on a suspension of isolated spleen cells transferred to newly born rabbits[5].

One of the inhibitors selected was 6-mercaptopurine, in an attempt to verify the working hypothesis that ribonucleoprotein, which is responsible for the synthesis of specific protein (antibody) during the productive phase, is itself synthesized during the inductive phase[6]. In earlier experiments 6-mercaptopurine had been used to inhibit antibody formation in adult rabbits immunized with *Salmonella paratyphi B* antigen[7]. Using *S. paratyphi B*, antibody formation was not inhibited even by toxic doses of 6-mercaptopurine, evidently because this antigen evokes a secondary reaction. When Schwartz, Stack and Dameshek[8], however, later used protein antigen ('primary reaction'), they obtained complete inhibition of antibody formation by 6-mercaptopurine.

In the present experiments, 1 ml. spleen cells isolated by the method described in a previous paper[5] was administered intraperitoneally to young rabbits; 1 ml. contained 50 × 10^6 cells. In all the experiments 6-mercaptopurine was administered subcutaneously in amounts of 0·5 mgm./100 gm. body-weight daily.

In the first experiments, cells from normal unimmunized donors, mixed *in vitro* with heat-inactivated *Brucella suis* antigen (7 × 10^8 micro-organism), were administered. In animals which received 6-mercaptopurine on the first five days after cell transfer, antibody formation was completely inhibited. Cells administered without the simultaneous administration of 6-mercaptopurine formed antibodies in the normal manner (Fig. 1).

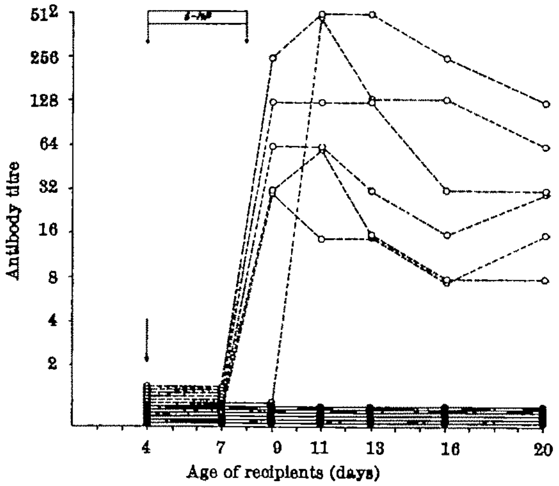

Fig. 1. 6-Mercaptopurine administered simultaneously with transfer of normal cells mixed with *B. suis* antigen *in vitro* (full line). The same cell suspension was administered without 6-mercaptopurine to control recipients (interrupted line)

In other experiments, cells from an immunized donor, that is, already forming antibodies, were transferred. The administration of 6-mercaptopurine in the same doses and at the same times did not prevent these cells from forming antibodies (Fig. 2). These results demonstrate that 6-mercaptopurine does not have an inhibitory effect if antibody formation has already developed (that is, during the productive phase).

In order to determine more precisely the phase of antibody formation as affected by 6-mercaptopurine, this substance was administered at different time-intervals after transfer of normal cells mixed with antigen *in vitro*. When administered 24 hr. after cell transfer, it inhibited antibody formation in every

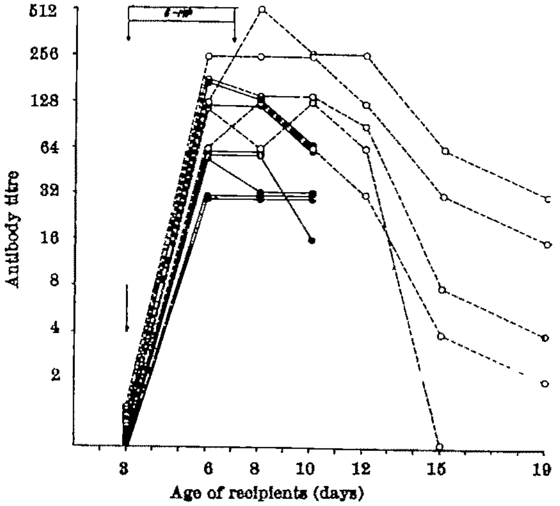

Fig. 2. 6-Mercaptopurine administered simultaneously with cells from previously immunized donor (full line). The same cell suspension was administered, without 6-mercaptopurine, to the controls (interrupted line)

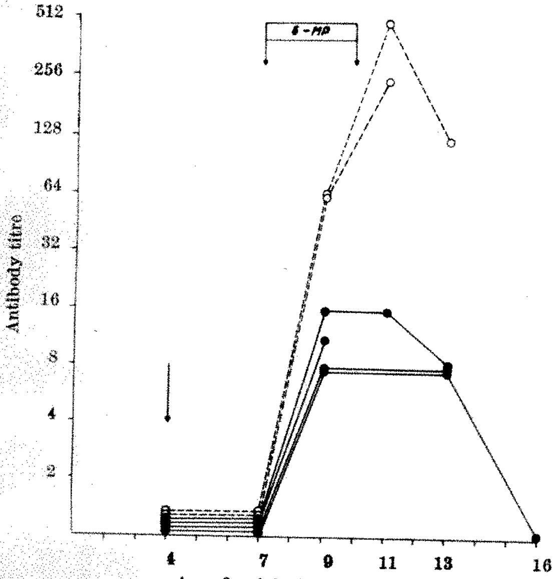

Fig. 3. 6-Mercaptopurine administered 72 hr. after transfer of normal cells incubated with *B. suis* antigen *in vitro* (full line). The same cell suspension was administered, without 6-mercaptopurine, to the controls

case. If it was administered 72 hr. after transfer, the transferred cells formed antibodies, although in low titres only (Fig. 3). Using a bacterial antigen, therefore, the crucial period for sensitivity to 6-mercaptopurine is 48–72 hr. after injection of the cells mixed with antigen *in vitro*; this corresponds exactly to the inductive period, as determined in tissue cultures[4].

It was usually found during these experiments that the dose of 0·5 mgm. 6-mercaptopurine/100 gm., which normally is tolerated well, was lethal for young animals to which cells already forming antibodies were transferred (Fig. 2). This is probably due to summation of the effect of 6-mercaptopurine and the metabolic demands of the transferred antibody-producing cells.

The results show that 6-mercaptopurine is effective during the inductive phase only; the mechanism of its inhibitory action supports the conception that processes during the inductive phase are associated with the synthesis of nucleoprotein. These results form part of a wider series of transfer experiments in which different types of inhibitors (for example, colchicine, ethionine) are used in an attempt to define exactly the conditions and metabolic processes of the inductive phase of antibody formation.

BIOLOGY

Myxomatosis in Britain

In his article, Dr. C. H. Andrewes[1] directs attention to the contrast between the host/vector relationship in Britain and Australia. When we have acquired further information about the biology of the rabbit flea (*Spilopsyllus cuniculi*) and also other possible arthropod vectors, we may find that a somewhat different set of factors comes into operation in Britain between major epizootics.

After the initial outbreak of the virulent type of myxomatosis, when the rabbit population at Ashton, Peterborough, was at its lowest ebb, the few survivors which were caught showed a greatly reduced individual flea infestation. It might have been supposed that, owing to the number of dead rabbits from which the fleas had scattered in search of living hosts, the remaining healthy rabbits, especially any immune survivors, would become progressively more heavily infested. But this was not so. All survivors examined six months after the first great epizootic harboured at the most four or five fleas each, quite frequently no fleas at all, or fleas other than rabbit fleas. In the year preceding the outbreak 500 rabbits examined from the same area showed a 100 per cent infestation-rate with a mean per rabbit of approximately 70 fleas on the small sample counted. Three years later, when rabbits were becoming more numerous at Ashton, rabbit fleas were again plentiful, although no actual counts were made at this time.

It therefore seems possible that the chief vectors during a big epidemic may be different from those between, or right at the end, of a big epizootic. Mosquitoes spread myxomatosis, at any rate to a limited extent, in Britain[1]; and it is probable that other winged vectors such as black fly (*Simulium*) are capable of transmitting the disease. During the period of reduced rabbit and flea population the winged vectors may well play the major part as agents of dissemination, and if this were so, the avirulent strains of myxomatosis would, between big epizootics, enjoy certain advantages similar to those described for these strains in Australia. When the rabbit and flea populations build up again, which they do fairly rapidly, the rabbit flea would assume once more its role as chief vector in Britain and consequently there would again be some evolutionary pressure in favour of a virulent virus.

Glucose-6-Phosphate Dehydrogenase Deficiency Trait in Nigeria

We were led to look for the presence of this trait in Nigeria because of the demonstration that 10 per cent of American Negroes are deficient in this enzyme[1] and the discovery that hæmolytic anæmia caused by certain drugs (for example, primaquine) develops only in the presence of this sex-linked inherited deficiency of red cell glucose-6-phosphate dehydrogenase[2].

We have applied the rapid screening test as described by Motulsky[3] to 204 male Nigerians of which 139 were Ibo subjects, all of them inmates of Uzuakoli Leprosarium, and 65 were Yoruba subjects attending University College Hospital, Ibadan. Assay for glucose-6-phosphate dehydrogenase[3] was carried out on all 20 persons found deficient by the rapid screening test, and on 18 normal subjects. Our results are shown in Table 1.

Table 1. INCIDENCE OF DEFICIENCY OF GLUCOSE-6-PHOSPHATE DEHYDROGENASE IN RED CELLS OF 200 MALE NIGERIANS

Tribe	No. examined	No. deficient
Ibo	139	9
Yoruba	65	11

The demonstration of the presence of the trait in Nigeria raises several interesting problems: (1) The suggestion made by Motulsky[3] that subjects lacking the enzyme may exhibit a relative resistance to falciparum malaria could be investigated by field-studies of children less than five years of age, and by a study of severely ill malarial children admitted to hospital. (2) The presence of the trait may determine the onset of hæmolytic anæmia induced by dapsone in Nigerian leprosy patients, the incidence of which is approximately 10 per cent (Davey, F., personal communication). (3) The tribal distribution of the trait will have to be assessed in a far larger group of unselected persons. (4) The presence of the trait in adult Nigerians should be looked for in cases of unexplained hæmolytic anæmia often summarily dismissed as 'blackwater fever'.

The co-operation of Drs. F. Davey and L. Hogerzeil in obtaining blood samples is greatly appreciated.

A New Record of *Mytilicola intestinalis* Steuer, a Parasitic Copepod of Mussels

SINCE the description of *Mytilicola intestinalis* by Steuer in 1902[1] from Trieste, it has been found in various localities of the Mediterranean and appears to have spread from this area to the Atlantic seaboard of Europe and around the British Isles[2]. Infection with this parasite has resulted in serious damage to mussel beds in many areas, with an attendant effect on the mussel industry[3]. Any information regarding the spread of this parasite is consequently of some importance. It is therefore interesting to record the taking of two female *M. intestinalis* in the Indian Ocean–Malacca Strait area, position 7° 12′ N., 97° 12′ E.

The two specimens taken (Fig. 1), approximately 8·5 mm. and 7·0 mm. long, were sufficiently distinctive to refer to this species rather than to either of the two other described species, namely, *M. orientalis* Mori and *M. porrecta* Humes. Dr. Krishnaswamy, of the University of Southampton, has kindly examined the specimens for me and agrees with the identification.

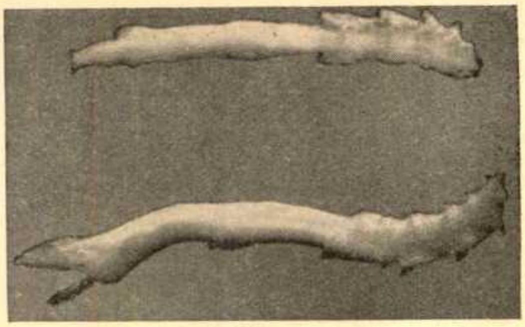

Fig. 1. Adult female *Mytilicola intestinalis*, 8·5 mm. and 7·0 mm. long

The circumstances in which the two specimens were taken were quite remarkable, both being taken in a surface plankton sample, during darkness, while the ship was drifting, hove to. The station was 50 miles outside the 100-fathom line and 67 nautical miles from the nearest land; the depth was 520 fathoms (951 m.).

There is no question of any contamination from European sources, nor is there the possibility that they had been carried from the shore since the water was clear blue and typically oceanic, as was the plankton. The possibility that they had been carried to the surface by currents is considered non-existent. Both my colleague on the cruise and myself are of the opinion that there was no growth of mussels on the ship's hull, although the possibility cannot be ruled out entirely (*M. viridis* L. is the common *Mytilus* of this area). Even if there were infected mussels on the hull it is difficult to explain how the parasites left the host and entered the net, which was some yards from the hull. The possibility that they had been regurgitated by a mussel-eating fish or bird is discounted in view of the excellent condition of the specimens. That adult female *Mytilicola* can be planktonic appears doubtful since the parasite has so far been taken only inside the mussels and never free.

However this may be, the occurrence of this species in the Malacca Strait extends its range of distribution, and increased collection in other areas may well prove the species to be more widely distributed than was hitherto known.

First Successful Hybrid between the Two Jute-yielding Species, *Corchorus olitorius* L. (Tossa) × *C. capsularis* L. (White)

ALTHOUGH numerous attempts had been made in the past to cross the two jute-yielding species, namely, *C. olitorius* and *C. capsularis*, no success was achieved[1]. The recent report by Ganesan *et al.*[2] that following hybridization between the two species a few-celled embryo and few free endosperm nuclei are formed encouraged us to repeat the above crosses. The failure to obtain hybrid seedlings has been attributed by these authors to the degeneration of embryo and endosperm at an early stage of their development. An attempt was therefore made to induce the full

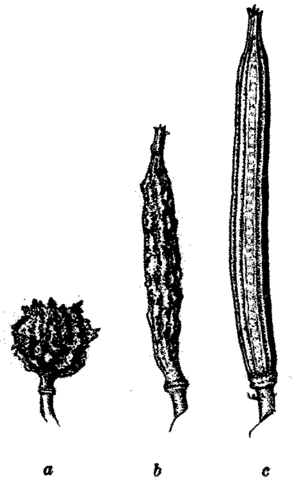

Fig. 1. Fruit shape and size in the hybrid and parents. *a*, Spherical fruit of *C. capsularis*; *b*, hybrid, note the projections and depressions along the ribs; *c*, 10-ribbed elongated fruit of *C. olitorius*, ribs are parallel and smooth. × ⅘

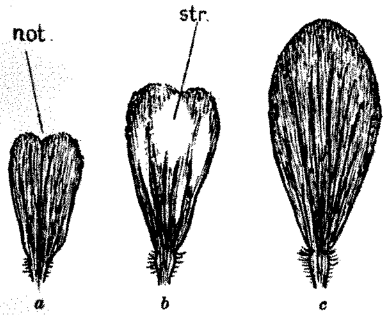

Fig. 2. Petal shape and size in the hybrid and parents. *a*, Notched petal of *C. capsularis*; *b*, notched petal of hybrid with irregular white streaks running from apex to base; *c*, petal of *C. olitorius*. *not.*, notch; *str.*, streak. × 5

development of the embryo and endosperm by the use of hormones. Following pollination, therefore, the pedicels of the flowers were wrapped with cotton which had been previously soaked in 300 p.p.m. 3-indole acetic acid. It was observed that the application of hormone increased the fruit set in the crosses and the seeds obtained therein appeared more developed than in fruits without hormone treatment. Of the 365 seeds obtained from 15 fruits in 115 crosses between *C. olitorius* (♀) and *C. capsularis* (♂), only 7 germinated, and of these only 3 grew to adult plants. No hybrid was obtained in the reciprocal cross.

All the 3 hybrids were slow growing, smaller in height and had a smaller base diameter compared with the parents. The hybrids showed dominance of the female parent in respect of the presence of a pair of stipules, shape of buds and fruits. In the character of leaf shape, B/L ratio of leaf, petal shape, presence of a notch on the upper margin of the majority of petals, irregularly ribbed fruits with alternate projections and depressions running along the ribs, the hybrids showed dominance of the *capsularis* parent (Fig. 1). The hybrids were intermediate in respect of serration of leaf margins, shape of bud and flower, colour and size of petals (Fig. 2), number of stamens and pollen diameter. In addition, the leaves of the hybrids showed areas of yellowish-green colour surrounded by normal green pigment. The petals showed irregular white streaks (Fig. 2*b*) running from the apex to the base surrounded by normal yellow pigment. The presence of these probably indicates the interference in the production of pigmentation brought about by new genic combination. Such disturbance in the production of pigmentation has been reported previously by Harland[3] in the progeny of interspecific crosses of *Gossypium* species, for example, *hirsutum–barbadense* crosses. The first few flowers in the hybrids withered away. Even selfing did not help in the setting of fruits. Almost 50 per cent of the flowers afterwards formed developed into fruits. These fruits varied a great deal in their size and the number of good seeds they contained.

All the 55 back-crosses to the *capsularis* parent failed. One hundred and twenty back-crosses to *olitorius* resulted only in the formation of 7 fruits.

All the diakinetic nuclei studied in the hybrids showed 7 bivalents. One of the 7 bivalents showed incomplete pairing. The two chromosomes in this pair were of unequal length. In all the diakinetic nuclei studied only one pair of chromosomes was found to be attached to the nucleolus. Except for the presence of two univalents in a small number of pollen mother cells, mostly 7 bivalents were seen at metaphase I. Lagging chromosomes at M_{I} and M_{II} were seen in only a small percentage of pollen mother cells. These irregularities were reflected in the presence of nearly 25 per cent sterile pollen grains.

It is known that cryptic structural hybridity obscures the true homology of the parental chromosomes of the hybrid as differences in the small segments of chromosomes do not interfere in the pairing of homologous chromosomes. Whether chromosome pairing in the hybrid was of this type or it really expressed the close homology between the chromosomes of the two species could not be ascertained due to the smallness of chromosomes.

The factor which led to the degeneration of embryo and endosperm at an early stage may have been counteracted by 3-indole acetic acid. The inhibitory effect being removed, the embryo and endosperm developed fully.

The climatic condition and weather in Hyderabad are different from those obtaining in Bengal and this may have also partly contributed to the success of the cross.

The hybrids have opened up new possibilities to jute breeders because by means of selection through a number of generations it may be possible to obtain a pure line with the desirable qualities of both the species combined.

Presence of *Aphelenchoides cocophilus* in the Roots of *Cocos nucifera*, the Coconut Palm

LITERATURE on red ring disease of coconuts, caused by the nematode, *Aphelenchoides cocophilus*[1,2], leaves the reader in doubt regarding the primary site of infection. Nowell[3] referred to the disease in Grenada as 'root disease' and considered the roots to be the primary site of infection. Later[4], he changed his opinion and regarded root infections as secondary to stem. Other workers[5,6] suggested that the disease was transmitted by the palm weevil, *Rhyncophorus palmarum* (L.). One of us[7] advanced the view that the disease frequently started in the base of the tree and suggested that infection might occur via the roots.

While making a series of observations on the disease in the field, we detected the presence of *Aphelenchoides cocophilus* in the roots of three apparently healthy coconut trees. As a result of this, we conducted a survey of a young plantation and examined the roots of 171 trees; root infections were detected in 55 of these trees; two of these root-infected trees were suffering from red ring infection of the stem.

The distribution of the worm was investigated in a number of individual trees and the maximum density was usually found 4–8 ft. away from the bole, and a continuous distribution of nematodes was detected for a distance of up to 14 ft. from the bole. The worms were usually found in the lateral surface roots down to a maximum depth of about 12 in. below the surface; the density of worms in these roots never approached that found in the stem tissues and rarely exceeded 200–300 worms per gm.

Trees, the roots of which were infected, frequently showed symptoms which we considered as indicative of root damage. The most outstanding symptom was a drooping of the bunches of nuts when these were present and a wilting and drooping of the lower leaves: there was no evidence of yellowing. Sometimes when roots of trees showing these symptoms were examined, *Aphelenchoides cocophilus* was not found, but many living specimens of *Rotylenchus* sp. were recovered.

Roots infected with *Aphelenchoides cocophilus* differ from healthy roots in that the root cortex which is firm in texture and white in colour in healthy roots assumes an orange-red coloration and becomes soft and spongy. These symptoms in the roots are not specific to *Aphelenchoides cocophilus* nor, for that matter, to nematode infection, but can also be induced by a variety of other causes.

Preliminary observations suggest that initial infection of roots occurs some distance from the bole, and spreads inwards; but further work is necessary to establish this. The presence of worms in the distal parts of the root system of apparently non-infected trees, when these roots mingle with the infected roots of adjacent trees, suggests the transmission of worms from tree to tree via the root system.

The plantation in question has been observed for four months since root infections were first detected. During this time 7 of the 55 root-infested trees have succumbed to red ring disease; in six of these, the distribution of red ring was consistent with infection starting at the base; the other was definitely the result of an infection starting in the crown. Of the 116 trees in which no root infection was detected only one tree has succumbed; in this, although the characteristic red ring only extended up a distance of 4–5 ft. and there were no petiole infections, yet worms were recovered from the root system for a distance of up to 10 ft. from the bole at one side. The majority of the root-infested trees which succumbed to the disease did so two or three months after root infection was first detected, so it is probable that *Aphelenchoides cocophilus* can remain in the root system for a considerable time before infecting the stem.

It is necessary to emphasize that the observations herein recorded are limited and do not as yet permit the drawing of generalized conclusions.

Effect of Micro-Organisms on the Development of Roots and Root Hairs of Subterranean Clover (*T. subterraneum*)

ALTHOUGH considerable information is available on the rhizosphere microflora and the influence of plants on this population, relatively little is known of the effects of these micro-organisms on the host plant apart from organisms such as *Rhizobium* spp., plant pathogens and mycorrhizas. It has been shown that root growth can be affected by the filtrates of cultures of rhizosphere organisms[1] and some antibiotic substances (polymyxin[2], streptomycin and griseofulvin[3]); however, in all these cases the products of microbial growth rather than the micro-organisms themselves have been added to the roots.

In the course of some general rhizosphere studies being conducted in this laboratory, it was observed that the root systems of plants inoculated with soil suspension appeared stunted and were more easily washed free of adhering sand than corresponding sterile root systems. Some of the results of subsequent studies are reported in this communication.

Seed of subterranean clover was surface sterilized with calcium hypochlorite, germinated on agar and non-contaminated seeds transferred to tubes of autoclaved sand and agar deeps. The sand was in 3 cm. × 20 cm. tubes to a depth of 5 cm. and brought to the equivalent of field capacity with plant nutrient solution[4]; three plants being grown in each tube. The agar deeps were in 1·5 cm. × 25 cm. tubes with 15 cm. of 1 per cent agar prepared with plant nutrient solution; one plant being grown in each agar deep. One half of the tubes were inoculated with 0·1 ml. of a 1-in-10 suspension of pasture soil, the other half receiving 0·1 ml. of a similar soil suspension which had been autoclaved. The tubes were transferred to a controlled-environment room which provided a 12-hr. light period each day of 1,000 ft.-candles on the plants with day and night temperatures of 18° C. and 15° C. respectively. The daily increments in growth of roots in agar were measured, while plants growing in sand tubes were harvested twice each week for root-length measurements and root-hair observations. Twelve replicates of each treatment were set up in the agar series and 12 plants harvested from each of the sterile and non-sterile sand treatments for each observation.

The mean daily root-length increments for sterile and non-sterile clover plants grown in agar (Table 1) show that elongation of the tap root was considerably reduced in the presence of micro-organisms, although there were no indications of root invasion or damage due to pathogens. The standard deviation for the daily measurements shown in Table 1 indicates a

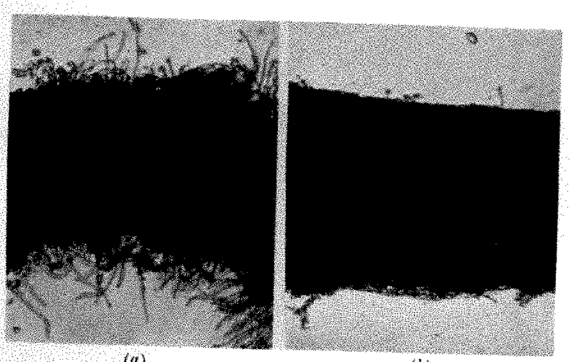
* Standard deviation.

much greater variability among the non-sterile plants which may be due to different types and numbers of micro-organisms on the different roots. The stunting effect of micro-organisms was also observed to a lesser degree in plants growing in sand. The growth of the plant tops did not seem to be affected by the micro-organisms on the roots, but this may not be so where the plant nutrients are not in luxury amounts as is the case in Hoagland and Arnon's nutrient solution.

Observations of the root hairs of plants grown in agar and sand showed that these were fewer in number and shorter in length in the non-sterile treatments. Fig. 1 shows the root hairs on the mid-root portions of sterile and non-sterile clover root systems grown in sand for six weeks. The effect was even more marked in the lower root portions—especially near the tip where the non-sterile were completely devoid of root hairs whereas the sterile roots supported large numbers of root hairs.



(a) (b)

Fig. 1. Root hair development on the mid-root portions of (a) sterile and (b) non-sterile subterranean clover roots in sand

Similar effects of micro-organisms on root development have also been recorded for tomato, *Phalaris tuberosa* and *Pinus radiata* growing in sand and agar, but the degree of stunting of roots and root hairs varied according to the plant and environmental conditions. This suggests a complex interaction between plants and micro-organisms. A more detailed report of the findings is to be published elsewhere.

RADIOBIOLOGY

Conditioned Avoidance Behaviour induced by Low-Dose Neutron Exposure

PREVIOUS studies have demonstrated that exposure to low-intensity γ- or X-rays over a period of 1 hr. or more leads to aversive behaviour in rats[1-4]. The avoidance behaviour is a learned response dependent upon an association between discriminative stimuli and exposure to radiation. The most sensitive test developed so far involves the use of distinctive taste stimuli. Rats will normally consume saccharin-flavoured water in preference to tap water. However, if a rat tastes this solution during a 6-hr. exposure to gamma-rays, resulting in a total dose of 30 r., it will exhibit a marked decrement in preference for saccharin which persists for several weeks post-irradiation. In contrast, an animal which drinks tap water during a similar exposure will maintain the normal preference for the saccharin solution.

The 60-in. cyclotron on the Berkeley California campus of the University of California was employed in this study to determine if fast neutron bombardment would establish avoidance conditioning in rats. The present work differs from previous studies in several important variables of radiation exposure. The animals were exposed for a brief period to fast neutrons at a relatively high dose-rate whereas in previous studies the animals were exposed for several hours to γ- or X-ray radiation at very much lower dose-rates.

Young male rats, approximately 90 days of age, of a Sprague–Dawley strain bred at this laboratory, were used in this study. Litter-mate animals were distributed into control and experimental groups in a balanced design. On three occasions during the two weeks prior to neutron exposure, the animals were processed through sham-irradiation procedures for the purpose of habituating them to manipulative disturbances, which included water deprivation, automotive transportation, confinement to individual irradiation chambers, and consumption of tap water under experimental conditions.

Approximately 24 hr. before neutron exposure, the animals were deprived of water to ensure consumption during the conditioning phase. On the following day they were transported to Berkeley (17 miles) for exposure to the cyclotron beam. Immediately prior to exposure a single plastic bottle was attached to each cage and the animal was allowed to drink during a 20-min. period. As specified by the experimental design summarized in Table 1, the bottles contained either tap water or a saccharin solution of 1 gm. per litre of water. Observations indicated that all the animals tasted the fluid at this time.

For exposure to fast neutrons, each animal was confined to a cardboard cylinder, 2½ in. in diameter by 7 in. in length. The 60-in. cyclotron supplied

Table 1. EXPERIMENTAL TREATMENT FOR EACH GROUP WITH RESPECT TO RADIATION DOSE AND TYPE OF FLUID CONSUMED PRIOR TO EXPOSURE

Group	No. of animals	Neutron dose (rads)	Fluid consumed before exposure
I	14	0	tap water
II	16	0	saccharin solution
III	16	7·5	tap water
IV	15	7·5	saccharin solution
V	14	15	tap water
VI	15	15	saccharin solution

neutrons by bombarding a thick beryllium target with 12 MeV. protons. The mean neutron energy was approximately 2 MeV. The animals were placed at isodose distances, 30 in. from the target. Groups III and IV received 7·5 rads at 10 μamp. beam current while groups V and VI received 15 rads at 20 μamp. Both doses were delivered in 4 min. The animals were turned 180° at the mid-point of exposure to provide a more uniform distribution of dose. Dosimetry for field geometry and exposure dose was made by measuring the fast neutron flux with sulphur threshold detectors as described by Tochilin and Kohler[5]. Gamma background was approximately 12 per cent of the neutron dose under the conditions of exposure used. Groups I and II were sham-irradiated in a corridor outside the water tank shield which surrounds the cyclotron. The environment in the corridor was comparable to that of the radiation exposure room.

The post-irradiation test for conditioned behaviour began approximately 40 hr. after the neutron exposure. The water bottle on the home cage was replaced by two bottles; one containing tap water and the other containing saccharin solution. The amount of fluid consumed from each bottle for a 24-hr. period was measured and the saccharin preference score for each animal is expressed as the ratio:

$$\frac{\text{saccharin solution intake (gm.)}}{\text{total fluid intake (gm.)}} \times 100$$

The results of the saccharin preference test following the neutron exposure are summarized in Table 2. The animals which drank saccharin-flavoured water prior to fast neutron bombardment for 7·5 rads exhibited an 80 per cent reduction in preference for the fluid as compared to the control groups ($P < 0{\cdot}01$). The effect of the 15 rad dose was significantly greater than the 7·5 rad dose ($P < 0{\cdot}01$). Two-thirds of the saccharin group exposed to 15 rads drank less than 1 ml. from the saccharin bottle during the 24-hr. test, but drank normal amounts from their tap water bottle. The animals which consumed tap water before the exposure to fast neutrons drank approximately 90 per cent of their total fluid intake from the saccharin bottle; a preference which was comparable to that of the non-exposed controls.

Table 2. THE MEAN SACCHARIN PREFERENCE SCORE FOR EACH GROUP DURING A 24-HR. TEST COMMENCING 40 HR. AFTER A SINGLE EXPOSURE TO FAST NEUTRONS

Neutron dose (rads)	Groups II, IV, VI (saccharin consumed before exposure)	Groups I, III, V (tap water consumed before exposure)
0	84·6 (4·4)*	90·6 (2·7)
7·5	15·4 (2·7)	89·9 (2·2)
15	4·7 (1·2)	87·3 (3·2)

* Standard error of the mean.

Neutron exposure is apparently an unpleasant experience which the rat associated with the taste of saccharin so that its post-irradiation preference for this substance is altered. The dose employed to establish this avoidance is relatively small; a single total-body dose of approximately 300 rads is required to produce deaths within 30 days post-exposure under the conditions employed in this study.

It may be concluded that fast neutrons as well as γ- or X-rays can be employed as an unconditioned stimulus to produce avoidance behaviour. Furthermore, in contrast to the previous studies which employed radiation exposures of several hours at low dose-rates, the neutron exposure lasted only a few minutes, indicating that the conditioning can be obtained under a wide variety of dose-rates and exposure conditions.

The opinions or assertions contained herein are those of the authors and are not to be construed as reflecting the official views of the Defense Department. We gratefully acknowledge the advice of E. Tochilin and B. W. Shumway concerning neutron dosimetry.

Estimation of the Cellular Lethal Dose and the Critical Cell Number for the *C3H* Mouse Mammary Carcinoma from Radiosensitivity Studies *in vivo*

IF it is assumed that irradiation of a tumour results in immediate or eventual sterilization of a given proportion of its constituent cells[1], that the magnitude of this effect is an exponential function of dosage[2,3], and that the ability of the residual viable cells to grow progressively depends upon whether their number exceeds that critical value below which their growth is effectively suppressed by host-resistance factors alone[4,5], then the radiosensitivity, or mean lethal dose, of the individual cells, and the critical cell number for the *C3H* adenocarcinoma growing under various conditions, can be estimated indirectly from observed data on the radiosensitivity of the tumour *in vivo*.

Taking the volume of a tumour cell to be of the order of 5×10^{-9} cm.^{3}, and allowing that the stroma and non-viable elements constitute roughly one-half of the tumour mass, we can safely assume each tumour cell to occupy a volume of 10^{-8} cm.^{3}, and accept this convenient unit as a standard 'cell' for the purpose of calculation. The validity of the following argument would not be affected if the actual mean tumour-cell volume differed somewhat from this assumed value.

If the rate of inactivation of tumour cells is exponential with dose, the residual cell population (A) after a given dose of radiation (D) is given by a function of the type:

$$A = N.e^{-kD} \tag{1}$$

where N is the initial cell population, and k a cellular radiosensitivity constant characteristic of the tumour and equal to the reciprocal of the mean lethal dose (synonymous with the 37 per cent-survival dose or D_0).

Table 1 summarizes the results of a series of experiments on the radiosensitivity of the *C3H* mouse mammary carcinoma under various conditions, based upon a total of 799 individual treatments, and representing the most accurate estimates of the relevant parameters currently available[6,7]. The respective median lethal doses for the tumour treated *in situ* are 7,500 rads in immunologically incompetent hosts previously exposed to whole-body irradiation

Table 1. CONSOLIDATED DATA ON THE RADIOSENSITIVITY OF THE *C3H* MOUSE MAMMARY CARCINOMA IN VARIOUS SITUATIONS

Host–tumour relationship	Dose*	Proportion cured	Cure-rate (per cent)	Estimated *LD*50	Standard error	Estimated critical cell No.
Immunologically incompetent hosts	9,000	12/18	67	7,500	± 250	1
	7,500	25/50	50			
Standard isogenic situation	7,500	54/54	> 98	5,660	± 40	25
	6,000	26/39	67			
	5,000	8/42	19			
	4,200	0/108	< 1			
Relatively 'immune' mice	5,000	12/26	54	4,800	± 100	200
	4,200	112/418	27			
	3,500	0/44	< 2			

* Rads: single exposure at 500 rads/min., 250 kVp. unfiltered, 2 cm. field at 25 cm. focus-skin distance, half-value 0·34 mm. copper.

or corticoid hormones[7], 5,660 rads in the standard isogenic host–tumour relationship[6], and 4,800 rads in mice rendered relatively resistant to the tumour by various 'immunizing' procedures[6,8]. In the case of tumour fragments irradiated prior to implantation (revised data[6] not included in Table 1), the dose yielding 50 per cent 'takes' was found to be 3,250 (± 110) rads.

From the data given it appears that the dose required to cure 37 per cent of tumours under conditions of minimal host resistance is about 7,000 rads, at which dose at least 1 viable cell must have persisted, on the average, for each tumour treated, that is, $A \nless 1$. Since these tumours were irradiated when they had reached a diameter of 1 cm. (volume 0·5 cm.³), the initial cell population $N = 0{\cdot}5 \times 10^8$. Substituting in equation (1), it follows that k cannot be greater than 0·00254 rad⁻¹, and that D_0, the cellular mean lethal dose, must be at least 394 rads.

An alternative estimate of this parameter can be obtained from the relative radiosensitivities of tumours (500 mm.³) treated *in situ* in unmodified hosts ($LD50 = 5{,}660 \pm 40$ rads), compared with tumour fragments (1 mm.³) irradiated before implantation ($LD50 = 3{,}250 \pm 110$ rads). If the dosage difference, $\Delta D = 2{,}400$ (± 120) rads, is entirely attributable to the 500-fold difference in cell-population, then $e^{-\Delta D/D_0} = 1/500$, and $D_0 = 385$ (± 20) rads. Since the two estimates are in close agreement, one could take the mean lethal dose for *C3H* carcinoma cells to be of the order of 390 rads.

From the foregoing data, the critical cell number, just permitting continued tumour growth in the mouse, can be computed. The median tumour lethal dose of 5,660 rads for 500 mm.³ growths treated *in situ* corresponds to a residual viable cell population of $0{\cdot}5 \times 10^8/e^{(5{,}660 \pm 40)/390} = 25$ (± 3) 'cells'. Similarly, for the 1 mm.³ fragments irradiated prior to implantation, the dose of 3,250 rads corresponds to a viable cell population of $10^5/e^{(3{,}250 \pm 110)/390} =$ 25 (± 7) 'cells'. A reasonable estimate, therefore, of the critical cell number, permitting 50 per cent growths in the normal *C3H* mouse bearing the standard isogenic mammary tumour, would be of the order of 20–30 cells.

In the group of relatively 'immune' mice, the estimated *LD*50 of 4,800 rads corresponds to a surviving population of more than 200 'cells'.

The cell-population concept, however, cannot in itself account fully for the variation in cure-rate with dosage. Given the average cell population for tumours treated at a particular dosage, factor A in equation (1), the proportion of cured tumours (P) presumed to contain less than Z cells (the critical number), is given by a Poisson exponential summation:

$$P = e^{-A} \sum_{x=0}^{z-1} \left(\frac{A^x}{x\,!}\right) \qquad (2)$$

Comparison of this function with the slope of the empirical 'probit' regression for the data shows the latter to be significantly greater. This difference reflects the variance of the observations, attributable in the main to the inherent dosimetric error, accounting for a 10 per cent coefficient of variation, and in part to minor genetic variation among individual mice.

In summary, the minimum number of cells capable of progressive growth in the three types of host–tumour relationship studied, that is, in the immunologically incompetent, the normal, and the 'immune' states, are of the order of 1, 25 and 200 tumour cells respectively. Assuming a constant radiosensitivity of the cells *per se*, the dose of radiation which is just sufficient to deplete the tumour cell population to the critical level will vary with different degrees of host resistance. Changes in radiosensitivity associated with various host–tumour combinations can, therefore, be accounted for in terms of differences in the corresponding critical cell assemblies.

The possibility that a low oxygen tension had raised the apparent lethal dose in our experiments cannot be excluded, although there is evidence that anoxia was not complete and that a similar degree of oxygenation existed both in the tumour treated *in situ* and in the fragments irradiated before implantation (unpublished data). Since complete anoxia may increase the inactivation dose by a factor of about 3[1], it seems unlikely that our estimate of D_0 would need to be reduced by much more than a factor of 2. On the other hand, consideration of the relative biological efficiency of the relatively soft radiation used in our experiments (half-value layer, 0·34 mm. copper) might necessitate an upward revision of the estimated D_0. Thus the mean lethal dose for the *C3H* carcinoma appears to be substantially greater than that reported for certain other tumours by more direct methods[2,3].

The foregoing reasoning is naturally based upon a quantal response to irradiation, namely, the lethal effect on tumour cells. It fails to account for the 'immunizing' effects induced by radiation-attenuated isogenic inocula, or for the graded reactions and interactions appearing in many tissues, organs and animals, which have been collectively described in terms of 'antigenic equivocation'[8]. It seems probable that the 'equivocation' and 'critical assembly' hypotheses are complementary. A detailed report on these experiments will be published elsewhere.

An Autoradiographic Study of the Distribution in Mice of Œstrogens labelled with Carbon-14 and Tritium

WE have examined the distribution in mice of the metabolic products of two œstrogens by an autoradiographic method which allows histological localization. It is of interest to use a 'physiological' dose, which Dodds[1] estimates to be close to 1 μgm. hexœstrol in the rat. Glascock and Hoekstra[2], using tritium-labelled hexœstrol in the goat and the sheep, found that the maximum quantity of the injected product which could be recovered did not at any time exceed 0·2 per cent in the uterus or 0·05 per cent in the vagina.

In preliminary experiments, we used œstrone-16-^{14}C of specific activity 2·7 μc./mgm., and in a second series œstradiol-17B-6,7-^{3}H (from C. E. Frost Co., Montreal, and the New England Nuclear Corp., Boston, respectively, and supported by a grant from the Fondation Fontaine), of specific activity 3·85 mc./mgm. The doses were respectively 1 mgm. œstrone-16-^{14}C (2·7 μc.) dissolved in poppy-seed oil and 50 μgm. œstradiol-17B-6,7-^{3}H (200 μc.) dissolved in olive oil, per animal. Female mice, weighing 25–30 gm., were injected at arbitrary stages in the œstrous cycle. The animals were killed after ½, 1½, 4 and 20 hr. in the first series, and after 3, 4, 6 and 12 hr. in the second. Fragments of the uterine tubes, the kidneys and the liver, and the whole of the ovaries were taken out. After fixation for 4 hr. in 10 per cent formaldehyde, two series of biopsies were prepared: the first was washed in water for 1 hr., the other for 12 hr. Because paraffin embedding was unsuitable, owing to the solubility of œstrone and œstradiol in alcohol, sections (20μ) were cut from material frozen with carbon dioxide. The sections were spread on gelatin-covered slides and treated for track autoradiography with nuclear emulsion Ilford *G* 5[3]. They were exposed for 6–10 days, developed and then stained with 'Unna'. Uninjected mice and mice injected with the solvent oils were treated similarly.

The results of the first series were entirely negative (œstrone-16-^{14}C). We observed no localization of β-tracks which could be attributed to the injected material. This failure is not surprising considering the small amount of radioactive material injected (2·7 μc.) and the fact that œstrogens are rapidly metabolized and excreted by the kidneys and the bile ducts[4].

In the second series (œstradiol-17B-6,7-^{3}H) when the animal had been killed after a short time (3–4 hr.) a localization of grains was observed in the kidneys and in the uterine tubes. These grains have the characteristic appearance of those produced by tritium β-rays. In the uterus, these grains are found in the cells of the endometrium and in the lumen of the glandular tubes, in contact with the apical pole of cells (Fig. 1), from which they are not removed by prolonged washing. However, Rengler[5] reports that, in rats injected with œstrone-16-^{14}C, the major portion of the radioactivity of the fluid from washings of the uterine lumen is present as a water-soluble component and that no radioactive steroids can be recovered from this fluid. Such a localization of grains was not observed after 6–12 hr.

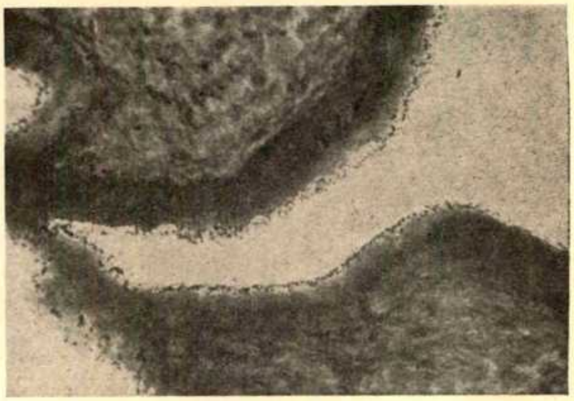

Fig. 1. Grains in the endometrial cells and in the lumen of the glandular tubes

In the kidneys, the grains are found in the periglomerular space and in the first part of the convoluted tubule, after 3–4 hr. (Fig. 2); but they are eliminated by prolonged washing. Similarly, after 6–12 hr., they are scarcely observable. This radioactive material, localized in the first part of the nephron, is therefore probably soluble, and seems to be filtered through the glomeruli. Budy[4] reports that the concentration of radioactive product recovered from the kidney is higher than one would expect, judging from the radioactivity of the urine; she attributes this result either to an effect of the blood, or to a re-absorption by the convoluted tubule. Our results favour the latter view.

In the liver and ovaries we have not observed any distribution of radioactivity which could be correlated with the structure of the tissues. It has been known for a long time that the liver plays an important part in the metabolism and the excretion of the œstrogens, and the absence of systematic localization might be related to the special histological structure of this organ, or to the moment when the animal was killed.

In the ovary, the lack of radioactivity in the present experiments is more difficult to understand, since Glascock[2] has found in this organ, for the same weight, half the radioactivity observed in the uterus.

The control sections were negative. One must, however, point out the presence of artefacts—fine grains and lines where the sections are disrupted.

In conclusion, the histological localization of the metabolic products of tritium-labelled œstrogens seems to be possible. Investigations with a more 'physiological' dose and examination within 2 hr. of injection should not be without interest.

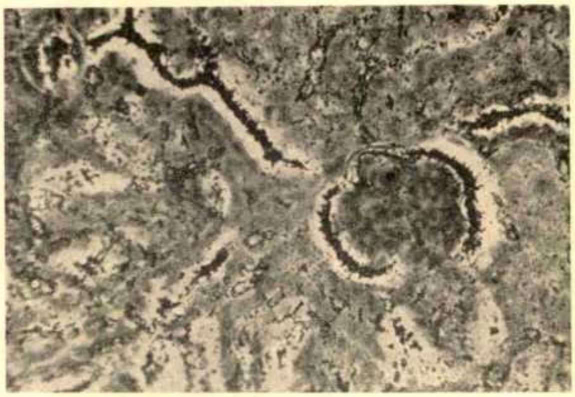

Fig. 2. Numerous grains in the periglomerular space and in the first part of the convoluted tubule

I wish to thank Prof. J. Brachet, who allowed me to study this question in his laboratory, and I am particularly indebted to Dr. A. Ficq for her advice and kind technical co-operation.

BACTERIOLOGY

Interspecific Hybridization among *Mycobacteria*

Experiments conducted in the first part of this work showed that a high degree of streptomycin resistance can be transmitted to *M. phlei* when a streptomycin-sensitive strain of this micro-organism and a streptomycin-resistant *BCG* strain of *M. tuberculosis* are cultured together in 'Tween' liquid medium.

Resistance to 50 μgm. streptomycin per ml. (S^r) was selected as marker in the *BCG* strain; the markers selected for *M. phlei* were pigment formation (Pig^+) and the capacity for growth on plain agar medium (Ag^+). The *BCG* strain may thus be described as S^r Pig^- Ag^-, while *M. phlei* is S^s Pig^+ Ag^+. Colonies of the new organism were picked from a selective medium: tryptose agar containing 50–1,000 μgm. streptomycin per ml. on which neither parent organism could grow when planted alone. Their inability to grow on this medium in 30 or more days served as control. The frequency of resulting streptomycin-resistant organisms was estimated to be 1–10 per 10^6 *M. phlei* units. Similar results were obtained in four experiments.

One of the strains obtained in the course of these experiments deserved special attention as it resembled the so-called 'atypical' acid-fast chromogenic *Mycobacteria*. This hybrid, in addition to high streptomycin resistance, showed yellow pigmentation (both in the dark and in the light) which, in contrast to that of the parental *M. phlei*, turned orange on prolonged cultivation. At 37° C. the strain grew on tryptose agar, as well as on 'Tween' agar or Loewenstein's medium within 5–12 days; at room temperature growth appeared slowly, in 12–20 days. No cord formation was seen. A high degree of pleomorphism and instability of traits other than the selected markers were found to be characteristic.

Since streptomycin was the only selected marker of the *BCG* strain used in these experiments, it was not possible to make any recombination analysis, or to assess the importance of a cell-to-cell contact (conjugation) in the transfer of streptomycin resistance.

Experiments were, therefore, carried out in order to shed more light on the mechanism of transfer: *M. phlei* was grown in the culture filtrate of the *BCG* strain; and *BCG* in the culture filtrate of *M. phlei*. Cell-free filtrates of *M. phlei* were never observed in these experiments to bring about changes in the *BCG* strain. Sterile culture filtrates of the *BCG* strain, on the other hand, conferred the streptomycin resistance to *M. phlei* cells. This could be repeated in three experimental series. The frequency, however, was 10^2 lower, that is, 1–10 per 10^8 *M. phlei* units. These findings indicate that the transfer of streptomycin resistance does not necessarily require cells as donors, and thus transduction may be the actual mechanism of transfer. (In the trials already carried out deoxyribonuclease treatment of the filtrate has not affected significantly its activity.)

These experiments, both those in which a *BCG* culture and those in which cell-free filtrates of a *BCG* culture were used as donors, disclosed also that: (1) The streptomycin resistance of descendant organisms increased to a level of more than 1,000 μgm. per ml. as against a level of 50 μgm. per ml. of the parental *BCG* strain of *M. tuberculosis*. (2) This high level of streptomycin resistance was attained in a single step, while the parent strain of *BCG* acquired the much lower resistance in four or five distinct steps. (3) In addition to this, a considerable portion of the resulting variants showed on isolation dependence on streptomycin. (4) Evidence was also obtained supporting the assumption that the transfer of hereditary traits is uni-directional, that is, from *BCG* strain of *M. tuberculosis* to *M. phlei*.

The results of the work described here appear to bear a resemblance to the findings made in the course of investigations of genetic transfer in various species of bacteria[1-5]. Studies on genetic transfer together with certain recently reported observations with respect to mutation[6-9] may, it is hoped, some day give an answer to the origin of atypical mycobacteria.

Role of *Hfr* Mutants in $F+ \times F-$ Crosses in *Escherichia coli* K12

Genetic recombination between mutant strains of *Escherichia coli* strain *K*12 is governed by a system of mating types[1,2]. The first two mating types to be discovered were called *F*+ and *F*−. In crosses the *F*+ parent donates genetic material to the *F*− parent. The progeny are predominantly *F*+. At the same time it was discovered that the *F* factor was infectious, that is, if *F*+ and *F*− strains were mixed and the organisms of the *F*− strain re-isolated, a proportion had become *F*+. It was therefore possible that the *F*+ state of the progeny was secondary and that any *F*-zygotes became infected by other *F*+ cells.

Then came the discovery of mutant strains of a new mating type known as high-frequency recombining (*Hfr*) strains[1,2]. Whereas *F*+ strains crossed with *F*− strains gave only one recombinant per

Table 1. DETAILS OF FOUR EXPERIMENTS ON SECONDARY INFECTION BY *F* FACTOR AFTER RECOMBINATION

Experiment	*F*− cells per plate	*F*+ cells per plate	Recombinant colonies per plate in first half	Percentage of colonies in first half *F*+	*Hfr* cells added per plate for second half	Recombinant colonies per plate in second half	Percentage of colonies in second half *F*+	Calculated percentage of zygotes in first half originally *F*+

n r., not recorded

10^5 parents, these *Hfr* strains when crossed with *F*− strains gave about 1,000 times this number of recombinants. The progeny of such crosses were *F*−. *F*+ organisms apparently mutate to the *Hfr* state and *Hfr* clones can be isolated from *F*+ cultures[4].

Jacob and Wollman suggested that these mutant forms were the agents in recombination in *F*+ × *F*− crosses, and that the *F*− progeny so formed were then secondarily infected by the *F*+ cells present. In support of their theory they measured the fluctuation in the number of recombinants obtained from several small *F*+ cultures. This suggested that the recombination was at least in part due to clones of *Hfr* cells. However, this type of evidence does not prove conclusively that cells of such clones are the only donors of genetic material in an *F*+ culture, and Lederberg has suggested that they are not[5]. Some experiments were designed to show whether secondary infection can, in fact, account for the high proportion of *F*+ progeny found in an *F*+ × *F*− cross.

In these experiments we have used *K*12 mutants 58–161/*F*+ (requiring methionine), *W*677/*F*− (requiring threonine, leucine and aneurin) and *Hfr* strains isolated from 58–161/*F*+. Washed log-phase broth cultures of these strains were suspended at approximately $2-5 \times 10^8$ viable organisms/ml. Each experiment consisted of two halves. In the first half the 58–161/*F*+ suspension was mixed with the *W*677/*F*− suspension in a proportion varying from 1 : 10 to 1 : 100. Aliquots of 0·5 ml. of this mixed suspension were immediately spread over each of several plates of minimal agar plus aneurin. The liquid was very quickly soaked up. For the second half of the experiment small numbers of *Hfr* cells were added to the mixed suspension before dispensing on to the plates. The actual numbers are given in Table 1. Both series of plates were incubated 36 hr. and the number of colonies counted. Neither parent could grow on this medium and the colony counts gave an indication of the recombination-rate.

Single colonies from these plates were streaked out on the same medium to obtain colonies free of parental cells and single colonies from these streaks tested for their mating type by crosses with *W*677/*F*− (streptomycin resistant). Those which would cross were recorded as *F*+ and those which did not as *F*−. In experiments 3 and 4 the colonies scored as *F*− were shown not to be chance contaminants by their ability to cross with 58.161/*F*+ (streptomycin resistant) but not with *W*677/*F*− (streptomycin resistant).

In each experiment the addition of the *Hfr* suspension increased the recombination-rate several-fold and therefore most of the progeny in the second half, having come from *Hfr* parents, must have been originally *F*−. The proportion of *F*+ progeny in the second half gives us, then, the rate of secondary infection under these experimental conditions. If it is assumed that the probability of secondary infection is the same in both halves of the experiment we can calculate the proportions of the zygotes in the first half which were originally *F*− and *F*+. This is given in the last column.

While prior mutation to *Hfr* undoubtedly accounts for some of the recombinants in an *F*+ cross, the proportion which are formed via *Hfr* mutation is not certain.

The existence of a significant proportion of *F*+ zygotes in the first half of the above experiment makes it evident that the genetic recombination in an *F*+ × *F*− cross is not mediated entirely by stable *Hfr* mutants of the type so far isolated, but that some *F*+ cells cross directly with *F*− cells.

I am indebted to Dr. D. Rowley and Dr. G. Furness for their interest and suggestions during this investigation, and wish to acknowledge a financial grant from the Medical Research Council.

Synthetic Polypeptide Derivatives with Anti-Bacterial Activities

A NUMBER of polypeptides composed of various basic amino-acids have been prepared by Katchalski *et al.*, and it had also been stated that agglutination of Gram-positive and Gram-negative bacteria was caused by these polypeptides, and bacteriostatic or bactericidal activity was observed depending on their concentration[1]. Stahmann and his co-workers[2] have reported that the multiplication of some viruses was restrained by poly-L-lysine.

From these observations and the fact that a number of naturally occurring antibiotics (for example, tyrocidine and polymyxins) have peptide structures and basic characters, it may be assumed that the microbiological activity of these compounds depends fundamentally on these structures and characters.

The synthetic polypeptides composed of basic amino-acids, however, cannot be employed for pharmacological use for they are soon disintegrated by the proteolytic enzymes of the higher organisms.

As previously stated[3], polymethyl-α-poly-L-glutamate can be converted with ethylenediamine into a water-soluble peptide derivative ('Polyanthin') which is resistant to proteolytic enzymes of allantoic liquid and at the same time efficiently hinders the development of bacteriophages T_5, T_6 and T_7. Its subcutaneous toxicity is about $LD50 = 850$ mgm./kgm. in mice.

The possible anti-tuberculous activity of this product has been investigated as follows (the 'Polyanthin' used in the experiments was kindly supplied by the Chinoin Chemical and Pharmaceutical Works Co., Budapest):

(1) To 1 ml. of a solution of 3,000γ 'Polyanthin' 0 01 mgm. (wet weight) of a three-weeks-old *H*37*Rv* culture was added. One part of the suspension was stored at room temperature, the other part at 37° C. Samples of 0·1 ml. were taken at different intervals and inoculated on Löewenstein–Jensen and Sula media. Other samples of 0·1 ml. were injected into pairs of guinea pigs. The culture media were examined after six weeks incubation at 37° C., while the animals were submitted to section and examined after eight weeks. . Both results are summarized in Table 1.

Table 1. Relation of 'Polyanthin' Activity to Time and Temperature of Application against *Mycobacterium tuberculosis*

No. of experiment	Time (hr.)	Temperature (° C.)	No of colonies	Degree of tuberculosis at autopsy
I*a*	16	37	many	generalized
I*b*	16	room	many	generalized
II*a*	24	37	many	generalized
II*b*	24	room	many	generalized
III*a*	72	37	10	moderately generalized
III*b*	72	room	many	moderately generalized
IV*a*	120	37	5	Only changes in regular lymphatic glands, and a few tubercules in spleen
IV*b*	120	room	4	
Control*	120	37	many	generalized
Control	120	room	many	generalized

* The controls were suspensions of tubercle bacilli in physiological saline solution.

The results show that 'Polyanthin' exhibits a bacteriostatic activity, increasing with the time of application.

(2) Thirty guinea pigs (about 350 gm.) were infected subcutaneously with 0·001 mgm. (wet weight) suspensions of *H*37*Rv*-Sula culture. (The suspension was prepared with rust-proof steel balls.) To each of 20 guinea pigs, once, in a single dose, a neutral solution of 60 mgm. 'Polyanthin' was given subcutaneously on the day following the infection. Ten guinea pigs were left for control. After 93 days the animals were submitted to autopsy. The degree of tuberculous change found in the different organs was estimated in whole numbers in the range of 0–4, and mean values were calculated. The following organs were examined: regulare lymphatic gland, retroperitoneal lymphatic gland, spleen, liver and lungs. The index for the control group was 3·4 and for the other group that got the 'Polyanthin' injection 1·4.

These experiments seem to show that 'Polyanthin' exhibits considerable anti-tuberculous activity. Further experiments are in progress.

Cystine as an Essential Amino-Acid for the Growth of a Strain of *Shigella dysenteriae* I (*Sh. shiga*)

In the studies on the nitrogen requirements for the growth of members of the genus *Shigella* in a chemically defined medium with various nitrogen sources added singly[1] a strain of *Shigella dysenteriae* 1 was found to grow only when cystine was present.

The basal medium consisted of 5 ml. each of salt solutions *A* and *B*[2], glucose 0·1 *M* and nicotinamide 10^{-5} *M*. To this was added, singly, the following: ammonium chloride (1 per cent), DL-glutamic acid, DL-phenyl alanine, DL-histidine, DL-lysine, DL-threonine, glycine, l-cystine, l-cysteine hydrochloride, DL-leucine, l-arginine, DL-aspartic acid, DL-alanine, DL-tryptophan, DL-valine, DL-*iso*leucine, DL-methionine, DL-tyrosine, DL-proline and DL-serine. The various nitrogen sources were dissolved in the basal medium with gentle heating. Cystine required the aid of hydrochloric acid and for tyrosine *N* sodium hydroxide was needed[3]. The amino-acids were present at 0·01 *M* concentration, except cystine and tyrosine, which were used at 0·0005 *M* and 0·002 *M* concentrations, respectively. The final *p*H of the medium was adjusted to 7·2–7·4; the medium was sterilized by autoclaving at 115° C. for 15 min. The inoculum of the organism was 0·1 ml. of an overnight peptone water growth diluted one in a hundred in sterile double-distilled water. Incubation was carried out aerobically at 37° C. and continued for seven days. If growth occurred during this period, one loopful of the growth was transferred to a second tube of the same medium. The nitrogen source was recorded as giving positive growth if three serial sub-cultures showed growth of the organism.

Cystine was the only amino-acid, among the nitrogen sources tested, in which growth of the strain could be obtained. As cysteine did not produce growth, further experiments were conducted and the results are shown in Table 1. The possibility of impurities in the cystine originally used was explored by using a preparation from another source of supply. The result was as before. The possibility that autoclaved cysteine, by producing colloidal sulphur and colloidal copper sulphide[4], may have caused inhibition of growth was eliminated by using filtered cysteine[5]. An attempt to grow the organism in cysteine containing medium which had been shaken aerobically at 37° C. for 6 hr., in order to abolish inhibition of growth by exogenous cysteine[6], was unsuccessful. There is a possibility that insufficient amounts of cystine were formed from oxidation of cysteine, for in a medium containing 0·02 mgm. of cystine per ml., as used by Proom in the study of the nutrition of Providence strains[7], the strain of *Sh. dysenteriae* 1 did not show any growth.

Johnson[8] suggested that cystine had a nutritional role for a strain of *Sh. dysenteriae* 1 investigated by him. The results of the present investigation in

VIROLOGY

Persistence of Herpes Simplex Virus in HeLa Cells

PERSISTENCE of herpes virus in cells cultured *in vitro* might provide a suitable model for investigating the phenomenon of latent herpes infection in humans. During a study on the interaction between herpes virus and HeLa cells, it was observed that an extensive cytopathic effect eventually resulted from inoculation of a monolayer culture with the *HFEM* strain of herpes virus[1,2]. A few isolated cells sometimes survived, however, and if growth medium containing antiviral serum was added, colonies grew from these surviving cells, leading eventually to a large population. These recovered cells were apparently healthy and grew as well as the original HeLa cells : there were no gross morphological differences such as those described by Vogt and Dulbecco[3], who studied cells recovered after poliomyelitis infection.

Despite continued growth in the presence of high-titre antiserum, however, the recovered cells were found to carry herpes virus for at least nine months, involving 29 subcultures. The presence of the virus was indicated by the appearance of typical microscopic foci of infected cells or plaques, from which virus could be isolated. These plaques appeared whether or not there was antiserum in the medium. When antiserum was present, however, the plaques remained localized and did not increase in number. It was therefore possible to deduce that there was one plaque-forming unit (presumably an infected cell) in approximately 10^5 cells. If antiserum was removed from the medium, the foci became larger and eventually confluent, with release of infective virus into the medium. No infective virus has been isolated from medium or cells at times when no plaques were visible.

By taking a small population of recovered cells it was possible to grow a sub-line which did not give rise to plaques spontaneously, even in medium free from antiserum. This sub-line was compared with the original HeLa cells for susceptibility to virus recovered from a single plaque in the recovered cells and then grown in chick cells to form a virus stock. With a large dose of virus, the virus-free recovered cells underwent a confluent cytopathic effect with release of virus. Comparative infectivity titrations in the recovered cells and the HeLa cell stock indicated, however, that 10–100 times as much virus had to be present to infect a recovered cell as that required to infect a stock HeLa cell.

The mechanism of persistence of herpes virus in recovered cells has yet to be elucidated ; but the susceptibility of these cells to virus, although reduced, does not suggest a situation resembling temperature bacteriophage, and it is also unlikely that auto-interference of the type studied by Henle *et al.*[4] could be the explanation. It is possible that persistence is due simply to the very slow spread of virus in the selected population of less-susceptible cells in the presence of inhibitory medium. This would resemble persistence of poliomyelitis virus in partially resistant HeLa cells, studied by Ackermann and Kurtz[5] and Vogt and Dulbecco[3]. Unlike the poliomyelitis-infected cultures, however, the recovered cells continued to carry herpes virus in the presence of strong antiviral serum. This is in keeping with the known ability of this virus and the related *B* virus of monkeys to spread between contiguous cells in antiserum[6,7].

This work was carried out with a "Juan March" Research Grant.

Monday, January 25

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. M. Paskins: "Transistors in Switching Circuits".

Radar and Electronics Association (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7.30 p.m.—Mr. J. C. G. Gilbert and Mr R. S. Roberts: "The Problems of Technical Reviewing".*

Tuesday, January 26

University College (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. R. W. R. Rutland "Radioactivity in the Earth's Crust".*

University of London (at Queen Mary College, Mile End Road, London, E.1), at 1.30 p.m.—Prof. J. D. Bernal, F.R.S.: "The Liquid State".*

University of London (at the Imperial College of Science and Technology, South Kensington, London, S.W.7), at 1.30 p.m.—Mr. Ernest Gellner: "The Barbarian Scientist ?"* (Further lectures on February 2, 9, 16 and 23.)

Royal Society of Arts, Commonwealth Section (at John Adam Street, Adelphi, London, W.C.2), at 5.15 p.m.—Dr. R. Maclagan Gorrie. "Irrigation and Population in Pakistan, India and Ceylon".

Institute of Marine Engineers (at the Memorial Building, 76 Mark Lane, London, E.C.3), at 5.30 p.m.—Mr. R. Anscomb and Mr. F. Hutber: "Control and Instrumentation of Marine Reactors".

University of London (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Prof. J. Brachet (Université Libre de Bruxelles). "The Rôle of Ribonucleic Acid in Protein Synthesis".*

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. J. V. Pulvertaft: "Auto-Immune Reaction".* (Fifth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on January 28, February 2, 4, 9, 11, 16, 18, 23, 25 and March 1.)

Society of Chemical Industry, Plastics and Polymer Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. J. F. Buckley: "Polymerization and Copolymerization of Itaconic Acid and its Derivatives".

Society of Instrument Technology (at Manson House, 26 Portland Place, London, W 1), at 7 p.m.—Symposium on "Flame Failure Detection". Mr. D. H. Surgeoner: "A Review of Current Flame Failure Devices"; Mr. D. Richards: "Applications of Flame Failure Equipment".

Wednesday, January 27

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 2 p.m. and 5 p.m.—Symposium on "Geological Implications of Recent Geophysical Work in the British Isles".

British Computer Society, London Branch (at the Northampton College of Advanced Technology, St. John Street, London, E.C 1), at 2.30 p.m.—Dr. G. G. Macfarlane. "Storage Elements for Very High Speed Computers".

Institution of Electrical Engineers, Electronics and Communications Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. A. Clow: "The Oral Presentation of Scientific Material".

University of London (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Prof. J. Brachet (Université Libre de Bruxelles) "The Rôle of the Cell Nucleus in Ribonucleic Acid and Protein Synthesis".*

Challenger Society (at the Linnean Society, Burlington House Piccadilly, London, W.1), at 5.45 p.m—205th Scientific Meeting. Mr. W. H. Dawbin: "Whales and Whaling in the South Pacific Ocean".

Institution of Mechanical Engineers (at 1 Birdcage Walk Westminster, London, S.W.1), at 6 p.m.—Dr. J. J. McMullen "Technical and Economic Aspects Covering the Ocean Transportation of Liquid Methane" (Thomas Lowe Gray Lecture).

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Dr. K. R. Sturley and Mr. A. E. Robertson: "Training for Operating and Maintaining Television Broadcasting Equipment".

Thursday, January 28

Challenger Society (joint meeting with Representatives from the Marine Laboratories (Development Commissioners' Scheme), in the Lecture Theatre, British Museum (Natural History), Cromwell Road, London, S.W.7), at 10.30 a.m. and 2.30 p.m.—Scientific Papers.

Institution of Mining Engineers (at the Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 11.15 a.m.—66th Annual General Meeting.

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m—Mr. Wm. T. Stearn: "How Many Species of Flowering Plants have Taxonomists Yet to Describe ?"; Dr. W. S. Lacey: "A Botanical Visit to Central and South Africa".

Mineralogical Society (at the Geological Society of London, Burlington House, Piccadilly, London, W 1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. A. W. Lines "Radio Communications by Means of Satellites".

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. R. G. White: "Immune Cellular Reactions".* (Sixth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on February 2, 4, 9, 11, 16, 18, 23, 25 and March 1.)

University of London (at the School of Pharmacy, 29–39 Brunswick Square, London, W.C.1), at 5.30 p.m.—Prof. P. Blanquet (University of Bordeaux). "Ion Exchange Resins and Thyroid Metabolism". (Further lecture on January 29.)

Friday, January 29

Institution of Electrical Engineers, Electronics and Communications Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. B. Dyott and Mr. C. R. Russell: "Beam-Type Parametric Amplifiers—Some Aspects of Design and Use".

University College (in the Eugenics Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. L. Lehmann (University of California) "The Efficiency of Non-Parametric Tests". (First of two Special University Lectures on Statistics. Further lecture on February 1.)*

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m—Mr. B. S. Shenstone: "Engineering Aspects of Man-Powered Flight".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. Edgar Wind: "The Academy of Leonardo Da Vinci".

Saturday, January 30

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. G. H. Francis: "Exploration in the Southern Andes of Peru".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Officer or Research Cadet (with an honours degree in agricultural science, and preferably special training or experience in soils research) in the Soils Division (Soil Physics Department)—The Director, An Foras Talúntais, 33 Merrion Road, Dublin (January 29).

Lecturer and an Assistant Lecturer (honours graduate in physics or chemistry) in Textile Chemistry—The Registrar, The Manchester College of Science and Technology, Manchester 1 (January 30).

Senior Technician in the new Department of Medicine, to take technical charge and assist with biochemical research—The Secretary, Royal Free Hospital, Gray's Inn Road, London, W.C 1 (February 1)

Research Fellow in the Department of Physics, for theoretical work in connexion with investigations now proceeding in the Department into the properties of solids at extreme infra-red and submillimetre wave-lengths—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (February 6).

University Demonstrator (with an appropriate honours degree and preferably postgraduate research or teaching experience) in Animal Physiology—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (February 6).

Junior Lecturer in Physiology—The Registrar, Trinity College, Dublin (February 8).

Lecturer or Assistant Lecturer in Statistics—The Registrar, The University, Leeds 2 (February 8).

Lecturer (preferably with a veterinary qualification) in Pharmacology in the School of Veterinary Medicine—The Registrar, Trinity College, Dublin (February 8).

Lecturer of Assistant Lecturer in the Department of Genetics, to assist chiefly with biometrical and population genetics—The Deputy Registrar, The University, Edgbaston, Birmingham 15 (February 10)

Assistant Lecturer or Lecturer (with special interests in inorganic chemistry) in Chemistry—The Registrar, The University, Sheffield (February 13).

Senior Lecturer or Lecturer in the Department of Electrical Engineering (Electronics)—The Registrar, The University, Liverpool, quoting Ref. CV/T (February 13).

Chair of Physics—The Registrar, The University, Southampton (February 15).

Lecturer or Assistant Lecturer in Pure Mathematics—The Secretary and Registrar, The University, Southampton (February 15).

Lecturer or Assistant Lecturer (with a first-class degree in mathematics and a strong interest in research in some field of applied mathematics) in Applied Mathematics—The Secretary and Registrar, The University, Southampton (February 15).

Scientific Officer/Senior Scientific Officer (Physical Chemist) (with a first- or second-class honours degree in physical chemistry or equivalent), at Warren Spring Laboratory, D.S.I.R., Stevenage, Herts, to work on application of radio isotopes in research problems being pursued in the laboratory—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting reference F.872/9A (February 15).

Chair of Botany at Westfield College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 19).

Chair of Chemistry at Westfield College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 22).

Chair of Mathematics at Westfield College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 23).

Scientific Officer (with a first- or second-class honours degree in chemistry) in the Department of Pedology, Forest Soils Section, for duties mainly concerned with studies on nitrogen in peat in relation to afforestation, as well as the development and application of methods for foliage analysis—The Secretary, The Macaulay Institute for Soil Research, Craiglebuckler, Aberdeen (February 27).

Assistant Lecturer or Lecturer in Organic Chemistry—The Secretary and Registrar, The University, Southampton (February 29).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Engineering, Pharmacology or Physics—The Secretary of University Court, The University, Glasgow (February 29).

Lecturer or Assistant Lecturer in Organic Chemistry—The Secretary and Registrar, The University, Southampton (February 29).

Assistant Lecturer in Chemistry—The Secretary, The University, Exeter (March 1).

Assistant Lecturer (preferably with an interest in theoretical plasma physics) in Physics—The Secretary, The Queen's University, Belfast (March 1).

Lecturer (with experience in one of the following fields . general physical metallurgy, metallurgy of surfaces, high temperature materials and ceramics) in the Department of Physical Metallurgy—The Deputy Registrar, The University, Edgbaston, Birmingham 15 (March 1).

Imperial Chemical Industries Research Fellows in Chemistry, Civil Engineering or Physics—The Registrar, Trinity College, Dublin (March 7).

Imperial Chemical Industries Fellows for research in Physics, Chemistry, Colloid Science, Biochemistry, Engineering, Metallurgy, Pharmacology, Chemotherapy, or related subjects—The Secretary-General of the Faculties, The University, The Old Schools, Cambridge (April 30).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Chemotherapy, Engineering, Metallurgy, Pharmacology or Physics—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 30).

Turner and Newall Research Fellow in Engineering, Inorganic Chemistry or Physics—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 30).

Agricultural Officer (Irrigation) (with a university degree in agriculture and preferably with experience in tropical irrigation research) in Kenya, to take charge of an irrigation research station and to be responsible for a research programme on irrigated crops and pastures—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/7/04/T.

Associate Professor or Assistant Professor (theoretical physicist, preferably with experience and main interest in the field of nuclear theory), to teach courses at the senior and postgraduate levels and to carry on research—The Head, Department of Mathematical Physics, University of Manitoba, Winnipeg, Manitoba, Canada.

Farm Manager (aged 25 to 35 years, with a university degree in agriculture) at Yundum Experimental Farm, Gambia, for technical and administrative duties in running an agricultural experimental station—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD/63/12/05/T.

Librarian—The Secretary, Oxford University Institute of Statistics, St. Cross Road, Oxford.

Master to teach Physics in the Upper School, including the Sixth Form—The Headmaster, St. Dunstan's College, London, S.E.6.

Organic Chemist (with a first- or good second-class honours degree and a good general knowledge of organic chemistry, and preferably postgraduate experience in steroid chemistry), to undertake the synthesis of labelled steroids—The Personnel Officer, The Radiochemical Centre, U.K.A.E.A , Amersham, Bucks, quoting Ref. No. 11/1959.

Research Assistants (2) (with a degree in chemistry or equivalent) in the Department of Chemical Technology, one for work on synthesis of nucleotides and analogous compounds and their biological application in cancer chemotherapy, and the other for work involving the synthesis of isotopically labelled organic compounds and the use of modern physical methods of analysis—The Registrar, Bradford Institute of Technology, Bradford 7.

Research Worker (with experience of research in the field of radioactivity), to be in charge of a newly established Isotope Unit—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8

Senior Lecturer (with an honours degree or equivalent in mechanical engineering together with industrial experience) in the Department of Aircraft Propulsion—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

University Extension Lecturers (qualified archæologists specializing in the earlier prehistoric periods) in Archæology—The Deputy Director (Extension), University of London, Senate House, London, W.C.1.

THE WANDERING SCHOLAR IN THE BRITISH COMMONWEALTH

A PASSAGE in the Queen's Speech at the opening of the new Parliament last autumn promised legislation to implement recommendations of the Commonwealth Education Conference, and in seconding the address, Mr. E. Gardner not only stressed the importance of seeing that to-morrow's leaders of the Commonwealth have the best and widest education we can give, but also urged the need of a two-way exchange of ideas and learning. He suggested that we should not only welcome Commonwealth students in our universities, our Inns of Court and technical colleges, but should also send our own students to the new universities of Africa and Malaya. In the same debate, Mr. Anthony Head urged much the same from a different point of view, suggesting indeed that it is vital for the West as a whole to overhaul its educational approach to the underdeveloped countries.

Two Bills have already been introduced during the new session which deal with the general problem. The first of these, the Marshall Scholarships Bill, which received its second reading in the House of Commons on November 6 and in the House of Lords on November 26, is essentially a Bill which doubles the number of Marshall Scholarships coming to Great Britain. In moving the second reading, the Joint Under-Secretary of State for Foreign Affairs, Mr. R. Allan, said that during the six years the scheme has been in force, 72 American scholars, including 20 women, had been selected from 37 different colleges and universities in the United States, of whom nine had come from Harvard, six from Stanford, California, and six from Princeton, New Jersey. Twenty-five of the scholars went to Oxford, twenty to Cambridge and fifteen to London, the remainder being spread over eight other British universities; the Marshall Aid Commission would like to see the scholars distributed among more British universities but felt obliged to offer them the university of their choice if vacancies existed there. All in all, the scholarships had achieved the success that had been hoped for, and many suggestions had been made to increase the number of scholars.

The Bill received a warm welcome in both Houses. In the Commons, Mr. P. Noel-Baker associated himself with the tribute paid to the work of the selection commissions in the United States and hoped that these commissions would continue to choose their scholars by regions. Selection simply on academic standards might lead to far too many of the scholarships going to the great universities of the eastern coast of the United States. Mr. P. Goodhart thought that at least one scholarship every year might with advantage go to a graduate of one of the American Service academies, or to the Virginia Military Institute, where General Marshall himself had studied. Mr. M. Stewart referred to the value of such interchanges in interpreting one country to another, and for that reason, he said, it is desirable that the Marshall scholars should be drawn, so far as possible, from every aspect of American life and that they should be given a very wide experience of Britain. It is right that we should respect the scholar's right of choice, but all the more important that we should build up both the performance and the prestige of the newer universities.

Other speakers were just as strongly in support of the scheme, but were anxious to improve it along these lines. Mr. M. MacPherson, for example, wondered whether it would be better to select one student from each State over a period of two years, and suggested that instead of universities in Britain as a group offering places to the twenty-four Marshall scholars, each university should be asked individually to offer a place in a particular subject which it wished to suggest. This might assist better use of some of the special facilities of particular universities, and also correct the concentration on too few subjects. At present students are mainly in social and political science, physics, chemistry and mathematics; of sixty students in the first five years, only two were taking applied science.

While these specific suggestions found little support in the debate, it was generally recognized as desirable to spread the students around so far as possible; and referring to the small number of Marshall scholars studying science, Mr. Allan, replying on the debate, pointed out that the National Science Foundation provides thirty-eight fellowships for Americans to study science. He also promised to put the points raised personally before the chairman of the Commission. In the House of Lords, the Minister of State for Colonial Affairs, the Earl of Perth, who moved the second reading, said that if experience showed that a greater number of scholars than twenty-four was desirable, the Bill would permit such an increase by Order in Council. Indeed, here even more than in the House of Commons, the debate stressed the value of the wandering scholar and the contribution to world understanding which the free intercourse of scholars could offer.

The second Bill, the Commonwealth Scholarships Bill, which received its second reading in the House of Commons on November 25, is the first of the measures promised in the Queen's Speech to give effect to some of the recommendations of the Commonwealth Education Conference. Specifically, it gives effect to the Commonwealth Scholarship and Fellowship scheme described in the White Paper and is intended to introduce a greater measure of academic mobility throughout the Commonwealth at a time when the men and women concerned are at the formative period of their professional careers. As Mr. C. J. M. Alport, Minister of State, Commonwealth

Relations Office, said in moving the second reading, it should provide a continuous exchange of ideas and knowledge by giving them access to the rich and varied intellectual resources and technical experience of the different Commonwealth countries; and he hoped it would go far to create in a very real and literal sense a Commonwealth of the mind, which, applied to the social, economic and political problems of our time, might provide answers to questions which those in the world of public affairs sometimes found so elusive.

The Scholarship and Fellowship Plan is outlined in the report of the Commonwealth Education Conference and the proposed arrangements for the administration of the scheme in the United Kingdom are described in a subsequent White Paper*. The plan is additional to, and distinct from, any other plan already in operation and is based on mutual co-operation and the sharing of educational experience among all countries of the Commonwealth. It is sufficiently flexible to take account of the diverse and changing needs of the countries of the Commonwealth and, while Commonwealth-wide, is operated on the basis of a series of bilateral arrangements to allow for the necessary flexibility. The awards are intended to be designed to recognize and promote the highest standards of intellectual achievement.

If the plan is to achieve its purpose, we must secure the widest possible variety of cultural exchange between all parts of the Commonwealth and so facilitate the development of a multilateral trade in ideas. The Commonwealth Scholarships will represent a system of awards to men and women from all Commonwealth countries who are of high intellectual promise and may also be expected to make a significant contribution to life in their own countries on their return from overseas. In the main, these awards will be made for a period of post-graduate study or research, to men and women capable of reaching the highest standard of intellectual achievement, and the ages of those considered for awards may vary according to the circumstances of particular countries. A limited number of Commonwealth Visiting Fellowships will also be made to senior scholars of established reputation and achievement.

The main emphasis will be on awards in the academic field; but the possibility is not excluded of some awards to other persons who play important parts in the life of their community. Because the awards will be made to persons of high intellectual attainment and held in institutions of higher learning, such institutions and members of the academic community who work in them should play an important part in selecting and placing the scholars and fellows. In the first place, the United Kingdom Government has undertaken to be responsible for the award of a total of 500 scholarships and fellowships to be held at any one time in United Kingdom universities, colleges of technology or other appropriate institutions, and Mr. C. J. M. Alport hoped that the first 250 of these would be available to be taken up at the beginning of the academic year in the autumn of 1960. The Bill creates a Commonwealth Scholarship Commission which will be solely responsible for selecting and placing the Scholars and Fellows. The Commission, of not less than ten or more than fifteen members, at least four of whom will be leading figures in the academic world, including a chairman designated jointly by the Secretary of State for Commonwealth Relations and the Secretary of the Colonies, in accordance with whose directions the Commission will act, will be assisted by a panel of forty advisers consisting of distinguished United Kingdom scholars and scientists. The Association of Universities of the British Commonwealth will provide the secretariat of the Commission, and the British Council will be responsible for paying the cost of passages, fees and allowances and for all arrangements for reception and welfare. When the plan is in full operation, it is expected that the 500 scholarships will involve annual expenditure of about £500,000, with some additional expenditure to supplement awards offered to United Kingdom citizens by other countries of the Commonwealth.

Mr. Alport added that each Commonwealth country is setting up a similar body with broadly the same duties as the Commission in Britain. That Commission will be solely responsible for selecting individuals for scholarships here or recommending candidates for scholarships overseas. He estimated the financial cost at £2,300,000 during the first five years, and urged that in future a period of service or study in the Commonwealth should be regarded not as a handicap, but as an essential qualification for a successful career in the professions, industry or technology in the United Kingdom. He also emphasized the importance of ensuring that students coming to Britain had an opportunity of entering fully into the ordinary life of the country, especially during vacations, and said that special attention would be paid to this by the British Council.

The Bill was warmly welcomed on all sides of both Houses of Parliament, and the debates were marked by much constructive criticism. Mr. H. A. Marquand stressed its value for the exchange of ideas and the exploration of ideas to free the human spirit. The importance of a wide distribution of students using the universities of the United Kingdom was stressed, and the Under-Secretary of State for Commonwealth Relations, Mr. R. Thompson, assured the House that it is intended that the Scholars should go to colleges of technology and not solely to universities. In the House of Lords debate on December 8, the Earl of Home, replying for the Government, anticipated that ultimately some 50 per cent of the Scholars might be studying technical subjects.

The need for special care in the reception of the Scholars was generally appreciated, and in a constructive speech Mr. Geoffrey Lloyd referred to the need to strengthen administrative arrangements in Britain to further the scheme. He suggested also that educational attachés might be useful and that we should consider their appointment to the offices of British High Commissioners and especially those in the younger Commonwealth countries. We must seek also to create an entirely new climate of opinion upon the whole question of Commonwealth education, and Mr. P. Goodhart regarded the Bill as a challenge to the people of Great Britain. The Scholarships would be a direct benefit both to Britain and to the Commonwealth as a whole only if the Scholars and Fellows were not allowed to feel lonely, unwanted and without friends.

* Commonwealth Relations Office Colonial Office, Commonwealth Scholarship and Fellowship Plan: Proposed Arrangements for the Administration of the Plan in the United Kingdom. Pp. 5. (Cmnd. 894.) (London: H.M. Stationery Office, 1959.) 6d. net.

In replying on this debate, Mr. R. Thompson remarked that the Government would make money available to remove some of the financial obstacles to the recruitment of teachers for the overseas service, and also said that the United Kingdom Government is planning that an additional 500 places in teacher-training establishments of all kinds should be made available for Commonwealth students over the next five years. There was some comment in both Houses on the absence of the Union of South Africa, which has so far not decided to participate in the scheme. Canada is to provide 500 scholarships and fellowships; Australia, 100; India, 100; Pakistan, 30; New Zealand, 25; the Federation of Malaya, 12; Ghana, 10; the Federation of Rhodesia and Nyasaland, 10; Ceylon, 6; and East Africa, 4. Mr. Marquand raised the point particularly in respect of the High Commission Territories in Africa, and thought that now that the universities of South Africa are closed to students from such territories their needs should be specially considered. Dr. H. King referred specifically to the provision by the students of the University of Southampton of a scholarship deliberately aimed at bringing to England some of the students whom the South African Government had denied proper opportunities of education.

At the Committee stage of the Bill in the House of Commons on December 3, comparatively few fresh points were raised: the importance of wide distribution of the Scholars, while giving due consideration to individual preferences, was again stressed; and, for the Government, Mr. C. J. M. Alport emphasized the importance of spreading these Fellows and Scholars as widely as possible over the academic life of the United Kingdom, both geographically and from the point of view of the subjects they came to study. The question of South Africa was considered rather more fully in the House of Lords debate on December 8. The Earl of Home, in introducing the Bill, added little to what had been said in the House of Commons, but stressed the need to ensure that Scholars or Fellows did not suffer in their careers through going abroad for a couple of years in their training. The question of South Africa, however, was raised in forthright manner by the Earl of Lucan. While we would welcome South African participation in the scheme and also South African students in Britain, he did not think it would be consistent with the conception of the Commonwealth on which the Education Conference was based to agree to British students going to South African universities which had been forced to abandon their old liberal traditions and conform to the present racial policy of the Union.

The Commonwealth, it is maintained in the report of the Conference, is a new experiment in human relationships, founded on a belief in the worth and dignity of the individual and a recognition of the value of freedom and co-operative action. Lord Brand, however, argued that it would not be an offence against human dignity to permit a Scholar from Britain to go to the self-governing University of the Witwatersrand, although the University's protests against the policy of the Union Government had proved ineffective. The Earl of Home, however, pointed out that if South Africa decided to come in and offered scholarships in the South African universities, the decision to apply for such scholarships would rest with the students themselves.

Nevertheless, as a side-issue of the debates, the policy of the South African Government towards the universities stood out in the same stark isolation to that of the remaining Commonwealth countries as it had done at the Conference on "Freedom and Responsibility: the Role of the Scholar in Society" arranged by the Committee on Science and Freedom, of which the report has just been published*. This was apparent in Dr. J. W. Cook's introductory paper on university traditions with particular reference to the British Commonwealth, in which he emphasized the importance of academic autonomy and academic freedom, of avoiding any steps which would hinder the free exchange of information, maintaining high academic standards and avoiding becoming involved in political controversy; and also in Dr. F. G. Malherbe's paper on university problems in a multicultural society, which showed factually how in South Africa the Government policy is depriving millions of non-whites of any chance of a university education. Dr. Malherbe pointed out that so far the academic freedom and autonomy of the existing universities continues to stand high; but a note on dismissals of staff at Fort Hare University College circulated with the report raises grave doubts as to how far this can continue.

The debates in Parliament on both these Bills show that Parliament generally is well aware of their importance and of the value of the wandering scholar in the life of the Commonwealth. It is realized, too, that such interchange can only be fully effective if supported by widespread co-operation both on the part of employers to see that the returning Scholars and Fellows are not affected adversely in their careers and equally on the part of the general public in the receiving countries to ensure that, especially in their leisure hours, they are absorbed freely and warmly into the life of the community. Perhaps too little was said as to the value of interchange, not merely in both directions between the United Kingdom and other Commonwealth countries, but also between the Commonwealth countries themselves. Nevertheless, neither the White Paper itself, the Conference report nor the debates in Parliament can leave anyone in doubt as to the value of these imaginative schemes in promoting understanding and goodwill and increasing the supply of trained people, or in developing in responsible men and women the qualities of judgment and wisdom, insight and sympathy, which the advance of civilization increasingly demands.

* Committee on Science and Freedom. Bulletin No. 13: The Scholar and Society—Report on a Study Group held in Tunis, April 1959. Pp. 144. (Manchester: Committee on Science and Freedom, 518 Wilmslow Road, 1959.)

RIVER STUDIES IN NIGERIA

River Studies and Recommendations on Improvement of Niger and Benue

By Nedeco, Netherlands Engineering Consultants, The Hague. Pp. ix+1000. (Amsterdam: North-Holland Publishing Company, 1959.) 140*s*.

ACCESS from the sea to the Benin ports of Burutu, Sapele and Warri in Nigeria has given much concern ever since about 1930. These ports constitute the link with the inland navigation of the extensive Niger and Benue river system, which provides a waterway of more than a thousand miles into the continent of Africa. At one time ships drawing up to 20 ft. could cross the bar of the Forcados estuary but in more recent years this estuary, along with the Escravos estuary, has only been able to accommodate ships drawing 12–14 ft. A continual decline in the draught available led the Nigerian Government to call in the Netherlands engineering consultant firm of Nedeco to undertake the Western Niger Delta investigation of 1952–54.

Soon after the Western Delta investigation was started preparations were made for a study of the possibility of improving the shipping conditions on the Niger and Benue Rivers. This eventually led the Nigerian Government to request from Nedeco a full-scale investigation of the Niger and Benue river system with the object of determining how the shipping conditions on these rivers could be effectively improved. The consultants were charged with discovering the characteristic nature and behaviour of the component parts of the river system; the composition by means of aerial and other surveys of a series of river maps covering the rivers downstream from Baro and Guara; of ascertaining the régime of the rivers and the vagaries of channel configuration and depths; and inquiring into the feasibility of possible future projects.

The work was commenced in 1954 and Nedeco has now issued a monumental tome of more than a thousand pages illustrated by several hundred diagrams and maps giving the results of the investigations of a team of twelve expert engineers who were stationed in Nigeria for three years. At first glance the report might be thought to be of interest only to those concerned with the practical problems of river navigation, but closer examination reveals that it will be of great value to many other experts. For the consultants found themselves obliged to consider matters which were not directly concerned with the technical problems of river regulation and river management. Since the Niger and Benue systems drain the greater part of Nigeria, the report effectively becomes an up-to-date account of the geography of Nigeria in which the physiography, geology, climatology and hydrology are all systematically considered as a background to the economic traffic on the rivers. It is these that are largely the life-giving arteries of the country. Of the various sections the hydrological naturally receives the most detailed treatment as this was, of course, a prime charge on the consultants. The report concludes with an account of the present problems of navigation, defects of navigability and recommendations for their improvement.

Because the report is so comprehensive it will be found of interest to geographers, geologists, geomorphologists, climatologists, hydrologists and hydraulic engineers: it brings together a great mass of new information and incorporates many new ideas. There can be few of these experts who will not find something of immediate interest in the report's thousand pages. The whole publication is beautifully produced and illustrated, and Nedeco is indeed to be congratulated on the appearance of such an impressive report.

The Western Niger Delta investigation during 1952–54 dealt with access to the ports of Burutu, Sapele and Warri and therefore only that part of the Niger Delta was studied and surveyed which lies west of the Bomadi Creek. Having undertaken the main Niger–Benue investigation it was only natural that the Government began to think in terms of a hydrological survey and investigation of the remaining part of the Delta. Accordingly, an agreement was signed in March 1958 between the representative of the Government of the Federation of Nigeria and of Nedeco for an Eastern Niger Delta investigation. Field-work for this is now under way, and the final report is expected towards the end of 1960.

W. G. V. BALCHIN

SOLUTIONS OF ELECTROLYTES

The Physical Chemistry of Electrolytic Solutions

By Prof. Herbert S. Harned and Prof. Benton B. Owen. Third edition. (American Chemical Society Monograph Series, No. 137.) Pp. xxxii+803. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1958.) 160*s*.

Electrolyte Solutions

The Measurement and Interpretation of Conductance, Chemical Potential and Diffusion in Solutions of Simple Electrolytes. By Prof. R. A. Robinson and Prof. R. H. Stokes. Second edition. Pp. xv+559. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1959.) 65*s*.

The Structure of Electrolytic Solutions

Edited by Walter J. Hamer. (Sponsored by the Electrochemical Society, Inc., New York, N.Y., and the National Science Foundation, Washington, D.C.) (Electrochemical Society Series.) Pp. xii+441. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1959.) 148*s*. net.

OF the three volumes under review, Harned and Owen's "Physical Chemistry of Electrolytic Solutions" and Robinson and Stokes's "Electrolyte Solutions" are new editions of well-known works that first appeared in 1943 and 1955, respectively. "The Structure of Electrolytic Solutions" is a collection of papers given at an Electrochemical Society symposium in Washington in 1957.

Unlike the second edition, which was largely a reprint of the first, the new edition by Harned and Owen incorporates some major revision and has been considerably extended. A section on irreversible thermodynamics has been added, and recent theoretical work on inter-ionic forces and their effects on both equilibrium and transport properties is included. Diffusion of electrolytes is fully discussed. The title "The Physical Chemistry of Electrolytic Solutions" is a pardonable exaggeration; many physico-chemical properties of such solutions are ignored. For example, there is little or nothing on reaction kinetics or spectroscopic properties and, although the adsorption of ions at the air/water interface is discussed, there is no mention of electrocapillarity or electrode reactions. The book is primarily concerned with the thermodynamics and transport properties of solutions and the central theme is the relation of such properties to ionic interaction. Broader and less tractable questions, such as standard free-energies and entropies of hydration, or the limiting mobilities of ions and their relation to ion-solvent interaction, receive less attention. Experimental data are fully discussed and tabulated, but experimental methods are only indicated in outline. In its own field this is a far more comprehensive monograph than any other, and much of its contents cannot be found elsewhere except in the original papers. The treatment is nearly always clear and precise, and the amount of detail given is very nicely judged, being neither too much nor too little. The earlier editions have become accepted as a standard and indispensable work of reference, and I do not doubt that the third edition will continue this tradition.

"Electrolytic Solutions", by Robinson and Stokes, is about half as long as Harned and Owen's book, and costs about two-fifths as much. It may be regarded as an advanced text-book (it certainly serves this purpose well), though in some respects it is rather more specialized in character than a text-book is expected to be. It covers a considerable part of Harned and Owen's territory, but generally in much less detail—with the important exception of experimental methods, which are here described fairly fully. In addition, more attention is paid to the interpretation of the properties of ions in terms of their interaction with the solvent. Profs. R. A. Robinson and R. H. Stokes have deliberately restricted themselves to the discussion of properties that seem to them to be fundamental, and as the sub-title indicates, the main topics are the measurement and interpretation of conductance (including transport numbers), chemical potential and diffusion. Thus, the book is by no means a text-book of general electrochemistry, and even in the narrower field of thermodynamics of electrolyte solutions, it does not deal with heats of dilution. But within their self-imposed limits, the authors have given a stimulating and well-balanced account of the subject, and their book can be recommended without hesitation. The first edition contained extensive tables of experimental results; these have now been enlarged and brought up to date and form a most useful collection of data. Elsewhere some minor changes have been made; for example, recent work on conductance in non-aqueous solvents has been incorporated.

The title "The Structure of Electrolytic Solutions" provides a wide umbrella, under which some twenty-seven papers have found shelter. They cover a big range, both in subject and in character. Some are essentially reviews of work with which their authors have been associated, others give new experimental results and a few are theoretical contributions. A few titles chosen at random include "Proton Transfer in Aqueous Solution", "Ionic Vibration Potentials", "Soret Coefficients", "Conductance and pH in Methanol–Water Mixtures", "Complex Ions in Molten Salts". It is a useful collection of papers and gives the reader a very fair picture of current trends in this field.

All three books are well produced and none suffers from an undue number of misprints or obvious errors. The price of Harned and Owen is formidable, but it is good value for money. J. N. Agar

TROPICAL MARINE MOLLUSCS FROM AMERICA

Sea Shells of Tropical West America

Marine Mollusks from Lower California to Colombia. By Prof. A. Myra Keen. Pp. viii+624+10 plates. (Stanford, Calif.: Stanford University Press; London: Oxford University Press, 1958.) 100*s.* net.

THE wealth of illustrated handbooks on American sea-shells available for coasts of the United States (and less expectedly for other areas) is in sad contrast to the dearth of European manuals. Though several faunal series provide identifications, by means of keys and descriptions, of animals in the North and Baltic Seas, no fully illustrated and reasonably comprehensive handbook on the sea-shells of any European coast has appeared for twenty-five years. For a British book, it is necessary to go back twice that time. Let us hope that the recently mooted European Malacological Union may stimulate the production of a work to challenge the best American models.

Among these, Prof. Keen's book stands high. Within well-chosen limits (excluding only shell-less forms, squid and cuttlefish, minute gastropods, stragglers and deep-water forms) she deals with even the rarest and the most dubious Panamic species, and illustrates all but a few. The coloured plates are decorative, while much of the value of the book lies in nearly seventeen hundred monochrome figures, of generally high quality. These are grouped on uniform pale grey backgrounds into half-tone plates, set in the text so that the illustration of a species occurs on the same pair of facing pages as the concise diagnostic notes. A few explanations of the figures, relegated to an appendix, would be helpful in the text. Though relatively small in bulk, the general matter is well conceived, touching on the ecology, affinities and exploration of the Panamic malacofauna, referring to general texts, and discussing the higher taxa. Ecological information on individual species is inevitably scanty, but the book itself will stimulate the observations by which the deficiency will be rectified.

In such a work, intended mainly for the knowledgeable amateur and the general zoologist, the precise systematic arrangement adopted is of secondary importance; but broader genera might have been adopted in a few highly split groups. Also, subgeneric names would tend less to emphasize difference at the expense of likeness, if merely listed at the head of the contained species, instead of being combined in every species name. Indeed, a slight over-emphasis on nomenclature is the most serious charge that can be levelled against Prof. Keen—whose identification of taxonomy with nomenclature will be ill-received by taxonomists and etymologists alike. That misleading technical term 'type' occurs repeatedly in the addenda though not in the glossary, but will not entrap those who read the suggested works on taxonomic practice. However, the discussion on the name *Mitra sulcata* is comprehensible only, and with difficulty, in the light of a new provision on the status of junior primary homonyms, which many will be surprised to find in the forthcoming edition of the International Rules of Zoological Nomenclature.

The addenda, in fact, are intended not for the general reader but for the systematic malacologist; who should acquire three additional pages, issued separately. They reinforce a bibliography of nearly six hundred titles, with every original reference to an included species, and a large number of original figures reproduced from inaccessible works, to make the handbook invaluable, especially to the isolated worker. Relatively few additional titles would be needed to provide references to the genera also, and publications of one author in one year could be distinguished in the text by means of the letters used in the bibliography. Perhaps these minor improvements may be incorporated in the successive editions which will certainly and deservedly be demanded.

I. C. J. GALBRAITH

BACTERIOPHAGES

Bacteriophages

By Mark H. Adams. With chapters by E. S. Anderson, J. S. Gots, F. Jacob and E.-L. Wollman. Pp. xviii+592. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 115*s*.

BACTERIOPHAGES are viruses made up of genetically active deoxyribonucleic acid enclosed within a protein shell, which seem to have no enzymes of their own, with the exception of some forming part of the specialized apparatus, the phage tail, concerned with their attachment to and penetration of the host. Yet the entry of the phage nucleic acid into a susceptible bacterium results in a complete change-over in the metabolism of the host, with synthesis of new enzymes, proteins and nucleic acids.

The advantages of such a system for the investigation of the mechanisms by which specific biosyntheses are controlled and performed are evident. Furthermore, phages, from the technical point of view, are much more convenient to work with than any of the other known classes of virus. It is therefore not surprising that in recent years the phage-infected bacterium has become a favourite experimental material for fundamental research in cell physiology, biochemistry and, perhaps most important, in physiological genetics, and that our knowledge of phages has increased enormously. Phage has been used as experimental material in such a variety of fields that the reports are scattered to an exceptional degree. The first text-book on phage to appear in English for many years has therefore been eagerly awaited. The work in question was begun some years ago by Dr. Mark Adams, of New York University College of Medicine, well known for his own researches on phage, particularly in the neglected field of their taxonomy, and for the course which he taught at Cold Spring Harbor for many summers; a course which served as an introduction to phage for many biologists and workers from other fields who have since contributed largely to our increasing knowledge of this subject.

At the time of Mark Adams's untimely death in 1956, his manuscript was unfinished. It has been completed by the addition of four chapters, planned but not drafted by Adams: on "Chemical Interference with Phage Growth", by J. S. Gots; on "Lysogeny" and on "Colicins", by F. Jacob and E.-L. Wollman; and on "Use of Phages in Epidemiological Studies", by E. S. Anderson. The eighteen chapters finished or partly written by Adams have been revised, brought up to date and completed by a panel of distinguished workers in phage research, the whole work being under the general editorship of A. D. Hershey.

The book as thus completed forms an excellent and reasonably detailed account of our knowledge of phage. The style and presentation are satisfactory, and even those without previous knowledge of the subject should have no difficulty in following the argument. Indeed, it may perhaps be said that at some points simplification has been carried too far; for example, the equation derived by Visconti and Delbrück for the frequency of a recombinant class among the progeny phage released after infection of bacteria by a mixture of phages of differing genotypes is given, but not its derivation. However, the qualitative treatment given will probably suffice for most readers. Those requiring more detail will find themselves well served by the extensive bibliography (some 900 references); it is to be regretted that not all the citations include the titles of papers. A glossary of terms used in the literature is also included in the volume.

Despite the rapid progress of research on phage, most experiments even now make use of a rather limited number of more or less standard techniques. One of Mark Adams's most useful services to the phage world was the publication in 1950 of a review entitled "Methods of Study of Bacterial Viruses", in which all these indispensable experiments and techniques were described and discussed. This most valuable compendium has been included as an appendix, with such additions and amendments as were needed to bring it up to date.

All the principal aspects of phage are dealt with, and it is satisfactory to be able to record that the earlier literature, mainly European, has not been neglected. The use of phages in epidemiology is the only application of phage described; their use in the treatment of bacterial infections, to which so much attention was given in the years immediately following the discovery of phage, is scarcely mentioned, an omission perhaps justified by the disappointing or equivocal results obtained, both in experimental and natural infections. In general, it may be said that the selection of results from the extensive literature has been admirably made, for while nearly every report of general importance is discussed or mentioned, the very large number of papers of only ephemeral or specialized interest are not referred to.

This work can therefore be warmly recommended (and indeed its high price seems to me its only major fault). It will certainly become, and long remain, the standard source of information on phage. It forms a worthy memorial to its principal author, both as scientist and teacher.

B. STOCKER

ELECTRONIC SECTOR-SCANNING ASDIC: AN IMPROVED FISH-LOCATOR AND NAVIGATIONAL INSTRUMENT

By Prof. D. G. TUCKER and Dr. V. G. WELSBY

Electrical Engineering Department, University of Birmingham

UNDERWATER acoustic echo-ranging systems are used extensively[1] in the form of vertical-beam echo-sounders for navigational and surveying purposes and for fish-location, and in the form of horizontal-beam asdics for fish-location and (especially during the Second World War) for the detection of submarines. In these systems considerable success is achieved in the simpler objectives of determining the depth of a level sea-bottom beneath a ship, of determining the depth of a fish shoal provided it happens to be under the ship, and—specially in the case of horizontal-beam systems—even in searching for fish-shoals. But the performance of all these existing systems is severely restricted by the fact that they are single-beam systems. A new system which we and our colleagues have developed retains most of the characteristics of the existing devices, but gives simultaneous information over a wide sector of search with good angular and range resolution. It therefore greatly aids the use of the echo-ranging system for searching, and speeds up and improves the accuracy of survey work. Moreover, it can eliminate the need for mechanical movement of the often heavy electro-acoustic transducer and thus greatly reduce the cost of ship-fitting operations.

In the existing single-beam systems the pulse is transmitted by a transducer (or loudspeaker), and received, after reflexion from the sea-bottom or whale or other object, by the same or a different transducer (this time used as a microphone). The time difference between transmitted and received pulses measures the range of the bottom or object, and is recorded on a chart by a stylus moving at a speed equal to the velocity of sound in water multiplied by the ratio of the width of the chart to twice the maximum range of detection. The transmission of the pulse marks the left-hand edge of the paper, and any echo received causes a mark at a point in the stylus sweep corresponding to the range of the object causing the echo. The paper is meanwhile moving at right angles to the stylus sweep, so that the next pulse transmission marks on a line adjacent to the previous one. The repetition of the echo in the same (or almost the same) position on successive sweeps causes a very great increase in the detectability of the echo if it is a weak one, and if the ship carrying the equipment is moving, the profile of the sea-bottom, or the shape of any object in the beam, is slowly traced out. To look in different directions means rotating the transducer(s), and while such a facility is usually provided in horizontal-beam asdics, it is not usually provided in echo-sounders.

The new system has the following distinctive features: (*a*) The receiving acoustic beam is relatively narrow and is swung continuously over a large sector by electronic means; the rate of sweep is so high that the sector is covered within a time less than the duration of the transmitted pulse. Thus, if the transmitting beam covers the whole sector, then echoes arising anywhere in the sector are received during each pulse repetition interval. (*b*) The received information is displayed on a cathode-ray tube in which one axis of deflexion corresponds to bearing (by being synchronized to the beam-swinging) and the other to range. The intensity of the spot indicates the strength of the echo.

This electronic sector-scanning system clearly enables the shape of the bottom profile over a certain length, or of any object in the sector, to be displayed instantly. The advantages of this in fish-location (and in identification of the fish) and in navigation and surveying may be considerable, and may be judged to some extent from the photographs of actual displays which accompany this article.

Outline of System

A schematic diagram of the system is shown in Fig. 1. The receiving transducer is n times the length of the transmitting transducer, and is divided into n sections, where n is the number of beam-widths (as measured between points where the power response

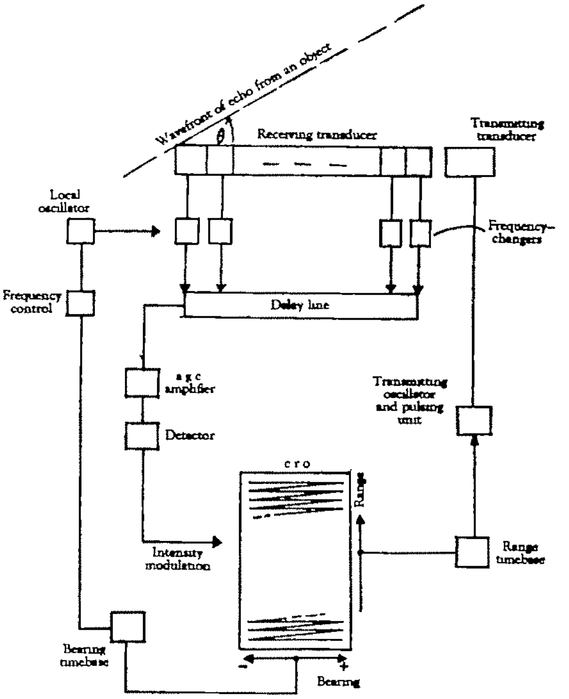

Fig. 1. Schematic diagram of electronic sector scanning system

has fallen to half) it is desired to contain in the scanned sector. If these *n* sections were connected to *n* corresponding, uniformly spaced, taps on the delay line, then the beam would be deflected by an amount dependent on the phase-shift in the delay line. The principle of this is readily seen: if an echo is received from a target on a bearing of θ relative to the perpendicular axis of the transducer, then the wave-front of the echo pulse lies parallel to the line shown in Fig. 1. The echo is received by the first transducer section before it reaches the second, and so on. Thus the echo signal received by successive sections is delayed in phase relative to the previous sections. If a peak output is to be obtained for this particular angle of arrival, then the delay line is required to insert compensatory phase-shift so that all the components of the combined output are in the same phase.

In the scanning system, frequency-changer equipment is inserted between the transducer sections and the delay line. The local oscillator which feeds all the frequency-changers is swept in frequency by the bearing time-base, so that the signal frequency received by the delay line varies over a range during every sweep of the bearing time-base. If then the delay line is made to have a phase-shift which varies over this frequency-range from negative values to positive values, the beam will be swept from left to right during each sweep of the bearing time-base. The latter also deflects the spot on the cathode-ray tube from left to right, so that signals received on any particular bearing are recorded on that bearing on the display. The range time-base works in the usual way, so that the position of an echo-spot on the tube indicates the position of the echoing object on rectangular axes of bearing and range. If the bearing scan is so rapid that it is completed within the duration of the pulse and is immediately repeated, no information is lost, and all directions in the sector are effectively looked at simultaneously, but with the angular resolution corresponding to the beam-width of the receiving transducer.

The technical and design considerations of this system have already been published elsewhere[2,3].

Results obtained with Nearly Horizontal Beam

The first laboratory experimental equipment, made in the University of Birmingham, was, through the courtesy and co-operation of the National Institute of Oceanography, given sea-trials in R.R.S. *Discovery II* during October 1958 and November 1959. On the latter occasion the equipment was used as a research tool by the staff of the Fisheries Laboratory, Lowestoft, in a study of fish migration. The ship was already equipped with a suitable electro-acoustic transducer designed and constructed by the National Institute of Oceanography. The primary object of the equipment and the trials was the location and study of fish shoals—some small fish shoals are shown on the display in Fig. 3*a*, *b*, *c* and *d*—but photographs of the way in which objects of navigational and surveying interest appear on the display were also obtained. A selection of these latter is shown in Fig. 2*a*, *b* and *c*. Fish can be distinguished from fixed objects, of course, by their movement and the variation of the shape of the shoals. For example, the shoal in Fig. 3*d* is the same as that in Fig 3*c*, but observed a minute or two later. The general speckled background in the photographs is the reverberation, or general back-scattering of sound from the sea-bed and waves. This, being random, never repeats from one pulse to another, and genuine targets can be easily distinguished, not only by their brightness, but also by their consistency from pulse to pulse.

The parameters of the equipment were as follows :

Beam-width = 1·5° in horizontal plane (between ½-power points)
Scanned sector = 12° in horizontal plane, that is, 8 beam-widths
Vertical beam-width = 10°
Pulse duration = 1 m.sec.
Frequency = 37 kc./s.
Transmitted acoustic power = 100 watts during pulse

A technical description of the equipment has been published elsewhere[3].

It should be noted that the heavy lines across the display in the range 0–100 yards approximately are due to the various side-lobes of the vertical beam-pattern striking the sea-bottom at ranges depending on their angle relative to the main beam. In general, no object on the bottom can be reliably detected until after the last of these lines. In an operational system the side-lobes of the vertical beam-pattern would probably be largely removed by suitable transducer design, and the early part of the range, up to the point where the main beam reaches the bottom, would be left clear for the detection of objects in mid-water. But in the experimental trials, the transducer was simultaneously being used for other experimental work which required the side-lobes to be present. The position of the beam in the vertical plane was, however, kept constant by a stabilizing mechanism using a gyro as reference, so that the angle of tilt of the main axis (quoted in Fig. 2) is a known constant for any series of observations.

The fact that there are only 8 beam-widths in the scanned sector in the experimental equipment accounts for the fact that even a 'point' object, such as the 18-in.-diam. sphere, extends over at least one-eighth of the bearing scan. An operational system might with advantage scan more than 20 or more beam-widths.

It is shown in a previous paper[2] how, at the edges of the scan, a 'target' just moving off at one edge begins to show at the other, but as movement proceeds further, the false echo extends with ever-decreasing strength. This is not serious for most purposes, but can be avoided by sacrificing some of the scan and placing a mask over the edges of the display. An illustration of the effect is shown in Fig. 4. It may be possible to get better results by more complex transducer arrangements, and this is being investigated. The effect is in some ways similar to 'side-lobe interference' in radar, but is more correctly known as 'diffraction secondary interference'.

The maximum useful range of detection is of the order 800–1,000 yards at the frequency chosen for the experimental equipment.

Use with Vertical Beam

When the transducer is tilted so that the beam points vertically downwards, the equipment becomes a scanning echo-sounder. If the beam is wide from fore to aft, but narrow from side to side, and scans from side to side, then the display will show, for each pulse transmission, the sea-bottom profile in some detail across the track of the ship. The ship's own motion forwards enables the profile along the track to be recorded. Thus *one* traverse of an area enables a three-dimensional picture of the bottom to be obtained—a result which shows an enormous saving of cost and time in surveying an area. It is, of course, the slant range which is shown on the display, and a correction must be made for true depth.

The vertical-beam operation is also useful for fish location and identification. Fig. 5 shows a photograph of the display obtained when a very scattered shoal of fish (probably herring) was passing through the sector. Individual fish are probably indicated by the smallest of the more distinct marks.

Conclusions

The results obtained by the biologists studying the movements of the fish will be published separately. It can be said, however, that the equipment has already proved itself able to give information on the horizontal and vertical distribution of the fish, and more particularly on their movements, which has probably not been obtained before ; and it may well prove an important research instrument in fisheries and hydrographic work. A system with much higher resolution in range and bearing is being developed, and it may eventually prove possible to study the movements of individual fish, of nets and other objects ; the need already exists.

To summarize, it is thought that the new electronic sector-scanning asdic has considerable possibilities in : (*a*) detection and location of fish ; (*b*) identification of fish by their shoaling habits, echo-strength and shape, etc. ; (*c*) research in fisheries work, for example, in studying the structure and internal and overall movements of fish shoals, and even of individual fish ; (*d*) navigation ; (*e*) hydrographic surveying.

We are grateful to our colleagues in the Electrical Engineering Department at the University of Birmingham for much of the research, design and constructional work which has been involved, and to the National Institute of Oceanography for some financial assistance, for help with the trials, and for the use of R.R.S. *Discovery II* and of the transducer. The interest taken in the work, the use made of the equipment, and the further financial help given by the Fisheries Laboratory, Lowestoft, together with much encouragement and interest on the part of the Marine Laboratories, Aberdeen, have proved a great stimulus.

---

THE HARWELL NEUTRON PROJECT

By DR. M. J. POOLE and DR. E. R. RAE

Atomic Energy Research Establishment, Harwell, Didcot, Berks

A LABORATORY has been set up at the Atomic Energy Research Establishment, Harwell[1], to exploit the possibility of using a linear electron accelerator as a pulsed neutron-source for time-of-flight studies. These studies increase our knowledge of highly excited states of compound nuclei.

The first machine to be used in this way produced electrons of energy 3 MeV., and was superseded in 1952 by a 15-MeV. machine, which produced photo-disintegration and photo-fission neutrons from a block of uranium which served as target for the electrons. In that accelerator the duration of the electron pulses could be made as short as 0·1 μsec. by pulsing the electron gun, and the beam current during a pulse was of the order of 25 m.amp. at 13·5 MeV. under full-load conditions (400 pulses/sec.). In these circumstances the rate of production of neutrons during the pulse was 10^{14}–10^{15} neutrons/sec.

The new laboratory has been designed around a much more powerful machine than either of its forerunners, since it is capable of providing a beam current during the pulse of the order of 400 m.amp. at 30 MeV. Using this in conjunction with a natural uranium target, a rate of emission of 2×10^{16} neutrons/sec. is possible. However, a further increase in the available neutron output has been obtained by building a special target (called the neutron booster) which is a multiplying sub-critical uranium-235 assembly, and by this means a ten-fold increase in the neutron output has been obtained. Thus the final rate of production of neutrons during the pulse is 3×10^{17} neutrons/sec. (A factor of 1·5 is accounted for by the difference in the production-rate of primary neutrons in natural uranium and uranium-235.)

In the time-of-flight experiments the neutrons are partly moderated in flat water tanks, 2 cm. thick, placed on three sides of the neutron booster. A layer of boron-10 metal placed between these tanks and the uranium-235 core prevents return of slow neutrons to the uranium-235 and so avoids serious distortion of the pulse shape. Some nine windows lead through the shielding and allow neutrons to pass down evacuated 'flight tubes' arranged radially about the neutron source and so reach the experimental apparatus. In this way the time-of-flight, and so the energy of the neutrons associated with some nuclear process, can be measured by recording the time-interval between the accelerator pulse and the time of arrival of the neutron. The recording of the times of arrival of the neutrons is carried out by multi-channel time analysers, one of which is associated with each individual flight path. The ability to carry out a number of time-of-flight experiments simultaneously in this way is one of the main advantages of a pulsed accelerator over a fast chopper as a pulsed neutron-source. The other advantage is the relative ease with which neutron pulses as short as 0·25 μsec. are obtainable.

Experiments in progress include measurements of neutron partial cross-sections for scattering, capture and fission, in addition to total cross-sections. From these measurements, the parameters of nuclear levels extending for several tens of keV. above the neutron binding energy are extracted. These parameters include the level-spacings, the neutron, radiation and fission widths, and the angular momenta. Another type of experiment is the study of the hard γ-rays arising from the capture of a neutron into various levels of the compound nucleus above the binding energy. An analysis of the relative strengths of these energetic γ-rays in different levels in the same compound nucleus demonstrates the random fluctuations that occur in the strength of a particular γ-ray transition.

The new machine should make possible a much more thorough investigation of the statistical laws governing the distributions of the parameters of nuclear levels, and may help to clear up certain mysteries which still surround the phenomenon of nuclear fission. In addition to these studies of neutron interactions, the investigation of a variety of photo-nuclear phenomena is also planned.

In the field of reactor physics, the pulsed-source method has been extended to allow the measurement of neutron spectra in reactor lattices. A knowledge of these spectra is of great importance in calculating the detailed performance of reactors, particularly the phenomena which govern the amount of permissible burn-up. Calculation is in principle possible once a detailed knowledge of the neutron-scattering law is known ; but neither experimental results nor methods of calculation are yet sufficiently developed to make this feasible, and recourse has to be made to direct experiment. In this method the target of the pulsed machine is placed inside a section of the lattice of interest, and the neutrons are moderated down to the spectrum characteristic of that lattice. This spectrum is then measured by the usual time-of-flight method.

The increased intensity from the new accelerator will make possible the performance of more complex experiments in which a pulse of neutrons is introduced into a moderator and the spectrum measured by using a synchronized neutron shutter (chopper) which opens a known time after the electron pulse. In this way it will be possible to follow the change in neutron spectrum during the last stages of slowing down, and to make a direct comparison with some of the theories of neutron thermalization available. It will also make possible the direct observation of the so-called 'neutron cooling', that is, the reduction in mean energy of neutrons in a moderator due to preferential escape of fast neutrons.

FORESTRY COMMISSION RESEARCH STATION

BEFORE 1946 the Forestry Commission had no research station; a limited amount of work on silviculture and mensuration was carried out by Forestry Commission staff at headquarters and elsewhere, and work on some other subjects, such as entomology and pathology, was done by specialists attached to other institutions.

In the summer of 1946, Alice Holt Lodge, a moderate-sized country house attached to an old Crown forest, was released from its war-time military occupation and opened as a Forest Research Station. By 1950 this building was proving inadequate for the expanding needs of the Station, and many of the offices were moved into huts. It was obvious that this could only be a temporary measure, and plans for more permanent expansion culminated in the spring of 1959, when a new wing, considerably larger than the building to which it is attached, was ready for occupation. This three-storey wing, together with a single-storey service block and a staff restaurant, has a total floor area of nearly 25,000 sq. ft. Construction is in the form of a concrete framework, supported on piles sunk 36 ft. into the Gault clay. The outer walls are made up of prefabricated panels, containing large timber-framed windows, with timber cladding below. The internal corridors are off-centre, giving rooms 16 ft. deep, suitable for the larger laboratories, on the eastern side, and rooms 12 ft. deep for offices and personal laboratories on the western side. The architects were Messrs. Cowper and Poole, of London.

The two buildings now serve as headquarters for all the research work of the Forestry Commission, with the exception of that on machinery and on utilization development, which is based on London. A branch station in Edinburgh, controlled from Alice Holt, deals with silviculture, genetics and to some extent management problems in Scotland and the north of England. However, much of the work centred on Alice Holt extends into Scotland. Although a silvicultural nursery, a tree-breeding nursery, several seed-orchards for the production of improved strains of tree seed, two poplar nurseries, a botanical collection of poplars and a pathological test nursery are attached to the Station, Alice Holt forest is not itself a research forest, and the experiments on which the staff of the Research Station are engaged are in forests and nurseries scattered all over England, Scotland and Wales.

Much of the field work is supervised by out-stationed research foresters, but nevertheless considerable travelling on the part of the Alice Holt and Edinburgh staff is also involved. In research nurseries or at centres where there is a large number of forest experiments, the Research Branch has its own labour forces, but much of the often considerable work involved in laying down forest experiments is carried out with the aid of the ordinary labour force of the forest concerned. It has been found that the progress and success of the work depend very considerably on the maintenance of a proper balance between the graduate staff planning and analysing experiments and the research foresters responsible for their lay-out, supervision and assessment in the field. There is no doubt that the existence of this body of skilled foresters provides a vital link in forest research, which is lacking, or at any rate insufficient, in some other forest research organizations even in countries where more money is available.

The new wing at Alice Holt houses those research sections which have need of laboratory space. Silviculture, with its subsidiary Sections, Ecology and Soils, occupies the whole of the top floor. Silviculture is concerned with all aspects of the cultivation of forest crops from the seed stage onwards. In the past, emphasis in Britain has inevitably been on nursery problems and on the establishment of plantations; but, as Forestry Commission plantings get older, work is becoming more concerned with matters such as the thinning, pruning and manuring of established plantations. Attention is now being given to methods of regenerating felled woodlands. This poses a number of difficult problems that will become more acute when earlier Commission plantings reach maturity. Felling will, of course, provide opportunities for change of species or variety, so that trials of different species, and in particular of different seed origins within those species, are still being actively pursued.

The Ecology Sub-section is concerned with studies of the site relationships of individual tree species, and with the investigation of sites where the establishment of satisfactory tree crops has proved difficult or impossible. The Soils Sub-section has two overlapping functions, analytical services for other sections and in particular for silviculture, and a programme of research into the nutrition of forest trees. Work has been particularly concentrated on foliar analysis and this is proving an essential part of the proper understanding of the many experiments on forest manuring now in progress.

On the second floor, but still under the control of the Silviculture Section, is the seed laboratory. This has a programme of work on improvements in seed-testing technique and on the storage of seed, but its main activity is the testing of all seed lots bought by the Forestry Commission, and for this purpose it is licensed as a 'private seed testing station'. Much of the seed which it tests is housed in the central Forestry Commission seed store, which occupies one end of the ground-floor of the new wing. This is not a research responsibility, but is housed at Alice Holt for convenience, and so that advice on storage and testing facilities are readily available. The store has three large refrigerated chambers, two for routine storage at 2° C. and one at −5° C. for the more difficult species. The total capacity of these chambers is 42,500 lb. of conifer seed. All the conifer seed bought from abroad or collected in England and Wales is stored at Alice Holt.

One end of the second floor is occupied by the Genetics Section. This could be more correctly described as a 'Tree Breeding' Section, since it is concerned mainly with practical problems on the improvement of forest trees. The selection of 'plus' trees from existing stands has already led to the formation of seed-orchards of Scots pine, Douglas fir, European larch and a few other species. Hybridization, followed by further selection, is being used to effect still further improvements.

The remainder of the second floor is occupied by the Pathology Section, which is concerned with the study and control of tree diseases. The work includes not only damage by fungi and bacteria, but also that due to non-living agencies, such as frost. At the moment, the control of *Fomes annosus*, the most serious cause of butt rot in conifers in Britain, is the major project of this Section. Other projects are top-dying of Norway spruces, a physiological disorder associated with increased exposure of the tree crown, and the testing of poplar and elm clones for resistance to bacterial canker and elm disease, respectively.

The Entomology Section, on the ground-floor, is engaged on investigations of a number of forest pests. It is normally concerned with the biology, including the occurrence of parasites, the forest status, which usually involves population sampling, and the control of each insect. In some cases, for example that of the pine looper moth (*Bupalus piniarius*), work has been particularly directed to finding the population-level at which the insect becomes a potential danger. In another case, that of the larch sawfly, work is directed to finding the effects of different populations and, therefore, of different degrees of defoliation, on tree growth.

The remainder of the ground-floor is occupied by the Photographic Section, which provides a common service to the rest of the Station, as well as to the Forestry Commission as a whole, taking most of the photographs required for illustration and record, and the slides necessary for lecturing purposes. The collection of more than 12,000 black-and-white photographs and nearly 7,000 colour slides is arranged numerically, but fully card-indexed on the International Forest Decimal Classification, so that photographs or slides on any particular subject can easily be located. The Section has produced several short films on forestry subjects.

The old building houses Administration, the Management Section, the Statistics Section, the Library, and a large room, which is used for meetings, conferences, lectures, etc.

The Management Section includes mensuration, which studies the growth of individual trees and of crops, and the methods of measuring them. It produces volume tables, yield tables, etc., for use in forest management. Management also includes the Census of Woodlands, and therefore has charge of all the data resulting from the census of all woodlands of 5 acres or more, carried out between 1947 and 1949, and of the census of hedgerow and park timber carried out in 1951. Working from this basis, sampling surveys for general purposes and local surveys for special purposes will be used in the future to provide more up-to-date information. Now that the hitherto overriding need for a strategic reserve of timber has become less acute, it is obviously desirable that more attention should be given to the economic background of forestry in Britain. For this reason, the Management Section now includes an economist, who is studying the nature and volume of the demand for timber and relating these to the costs involved in raising it. The Management Section is also responsible for assisting the Forestry Commission field officers in the preparation of forest working plans.

The Statistics Section is again a common service to the whole Station. The statistician advises on the layout of all experiments, thus ensuring that the resultant data are suitable for computation. The long-term nature of, and the large areas involved in, many forest experiments make care over design of particular importance. Computation is now done on a 'Pegasus' electronic computer by arrangement with the Royal Aircraft Establishment at Farnborough. The Section also carries out research into the application of statistical methods to problems of forest research and management.

The Library is a small one, containing some 3,500 books; but it receives all the principal forestry periodicals and has a considerable collection of reprints, reports, etc. It also carries out documentation work, resulting in a large card index of literature references on British forestry and on aspects of forestry abroad which are of interest to British foresters. There is also a series of classified information files. All filing is arranged according to the International Forest Decimal Classification.

The Forestry Commission encourages more fundamental work on some of its problems by means of grants to universities and other institutions. This has enabled the Alice Holt Research Station to concentrate the efforts of its staff very largely on the more immediately practical aspects of forest research. Thus, despite the relatively small staff—36 research officers and 107 research foresters in the Research Branch as a whole—there is a considerable output of work, mostly published in Forestry Commission publications (*Forest Records*, *Bulletins*, etc.) or in forestry and other scientific journals. A summary of the work of the Station, with brief accounts of grant-aided work at other institutions and with a number of short papers by the Research Station staff, is published annually as a Forestry Commission Report on Forest Research.

OBITUARIES

Prof. J. G. Wood

THE sudden death of Prof. J. G. Wood on December 8 last at the comparatively early age of fifty-nine has not only deprived the University of Adelaide of its senior professor but also has been a severe loss to biological work in Australia.

Joseph Garnett Wood was born at Mitcham, South Australia, on September 2, 1900, and educated at the University of Adelaide, where he obtained his first degree in the honours school of chemistry (1922). Fortunately he had shown interest and ability in botany during his undergraduate course, and in 1923 he became a demonstrator in botany. A programme of work on the vegetation of arid South Australia was beginning and the assistance of a chemist was vital. The saltbush (*Atriplex vesicaria*) which covers huge plains in the arid parts of the State had been termed a halophyte on insufficient evidence. Wood collaborated in the ecological work, which showed that the soils were not saline, except for the scattered salinas where *Atriplex* was absent. The plant had a high content of sodium chloride in the cells of its uncuticularized, tomentose leaves. Wood investigated the transpiration-rates of a number of trees and shrubs growing in the region and later showed that, in addition to having a low transpiration-rate, *Atriplex* was able to take up moisture through its leaves from saturated air. This work led to the award of an 1851 Exhibition scholarship, and Wood proceeded to Cambridge (Caius College) to read for a Ph.D. On his return to Adelaide in 1927 he was appointed lecturer, soon to be in charge of the Department. He was promoted to professor in 1935.

Work on the vegetation of arid South Australia had led to the generous donation to the University of an area of some 1,000 acres and small field laboratory at Koonamore, about 200 miles north of Adelaide in 1926. Wood collaborated in the work of the Koonamore Vegetation Reserve almost from the start. It is a tribute to his abiding interest in the arid flora that the Reserve and laboratory are still in regular use by the Adelaide Department for teaching and research.

Wood's contributions to botany fall under the heads of general ecology (his work on "The Vegetation of South Australia" (1937) has long been out of print), autecological work on arid plants and nutritional studies. Recently (1957) he and one of his research students have shown that sodium chloride is an essential micronutrient for *Atriplex vesicaria*. The nutritional studies have dealt with nitrogen and sulphur metabolism and the role of such micronutrients as copper, zinc and molybdenum. These are essential for crop production over large areas of leached soils in Australia but are not needed in the same quantities by the native sclerophyllous plants.

Wood had considerable organizing abilities. The fine range of biological buildings at the University owes much to his planning. Possessed of an alert mind and known for his fairness and even temper, much of his time and energy of late years have been spent on committee work. He was a member of the Interim Council of the Australian National University during 1948–51 and a Council member during 1952–55. He served on the Advisory Committee of the Commonwealth Scientific and Industrial Research Organization during 1951–59 and was chairman of the Board of Standards, of the Australian Journals of Scientific Research, and chairman of the Board of Research Studies of his University at the time of his death.

His recreations were largely connected with his home and garden. He had a good knowledge of Australian contemporary art and he himself painted. In 1930 he married Joan Hazel, who, with their three daughters, survives him. His one-time teacher and colleague can only join his many other friends in deploring his sudden passing.

T. G. B. Osborn

Prof. W. R. Fearon

William Robert Fearon, professor of biochemistry in the University of Dublin, died on December 27, 1959, aged sixty-seven years. The only child of a Presbyterian clergyman who had died when his son was four years old, he entered Trinity College, Dublin, in 1911. It was an indication of the intellectual versatility which was to characterize his life that he found some difficulty in deciding whether to read English or science. In the event he read natural science, in which he graduated B.A. with a Senior Moderatorship in 1915, securing also a Foundation Scholarship in Experimental Science two years later. He entered the Medical School during this period, but became so intensely interested in physiology and biochemistry that he interrupted his medical studies in the fourth year to do research work in nutrition in London during the First World War. Following this, he was awarded an exhibition to Emmanuel College, Cambridge, where he became one of the devoted band which Frederick Gowland Hopkins gathered around himself in the University Biochemical Laboratory. On his return to Trinity College, Dublin, in 1921, he was elected to a fellowship and thus began a period of almost forty years during which he enhanced the reputation of the College with his researches, delighted his students with the brilliance of his lecturing and entertained his colleagues by his sparkling conversation on almost any topic.

His literary bent had found recognition while he was still a student in the award of the vice-chancellor's prize in English verse, the University Philosophical Society's Gold Medal for English composition and the editorship of the College miscellany, *T.C.D.*, to which he was a frequent contributor. Throughout his career his clear, limpid style was to stamp everything he wrote whether scientific or otherwise. He was a master of the happy descriptive phrase which left an indelible impression. Always interested in motor-cars, he wrote of a visit to the Lancia showrooms in London during the early '30's that he had been taken for a drive in a car "that was the size of a cottage and cost as much as a house".

His early work was concerned with the formation of urea from protein, in the course of which he began to exhibit that facility for developing colour reactions which was to lead to so many papers in the *Biochemical Journal*. He loved to demonstrate these reactions to his colleagues or to visitors, and he must have discovered far more than he ever published. His interest in nutrition persisted and found its most recent expression in a survey of the fluoride content of Irish drinking waters. It was typical of his alert mind that he began this work more than ten years ago, at a time when others were only commencing vaguely to realize the possible practical significance of fluoride intake in dental health. For about six years before his death he had been interested in the ureides obtained from autolysed yeast. An outstanding contribution was his book, "An Introduction to Biochemistry", first published in 1934; he was working on the fourth edition when he last became ill. It is remarkable in that it is at once "An Introduction" which unfolds the subject to the student systematically and with the utmost clarity, and a comprehensive review that can be consulted with profit by the more mature worker.

Notwithstanding a rather shy disposition, he had wide interests outside his laboratory and, indeed, outside College. In the '20's he was the friend and associate of the literary and artistic giants of the time in Dublin—W. B. Yeats, Jack Yeats, George Russell (AE), Lennox Robinson, Oliver St. John Gogarty. He held the honorary professorship of chemistry of the Royal Hibernian Academy. His play, "Parnell of Avondale", was a success when produced at the Abbey Theatre nearly twenty years ago. He was an accomplished pianist and organist, and had an extensive knowledge of music.

One of the fascinations of knowing Fearon was the frequency with which, even after years of close friendship, one discovered new interests of his: a large stamp collection, to which he added regularly; his flair for cars, both vintage and modern sports—his own collection had included a Lancia, a Bentley and a Rolls; his real appreciation of the musical comedies of the early part of this century. In the same way, one learned with surprise, in 1943, that he was a candidate for a seat in the Senate of the Irish Parliament as a representative of the University of Dublin, for one had never been aware of his interest in matters political. Yet he continued to hold his seat to the end, and his colleagues in the Upper Chamber often expressed a high regard for him as a member.

William Fearon was a man of great gentleness of character but one who did not encourage intimacy, and not many of his friends knew him really well. Nevertheless, his passing will leave many gaps. He will be missed in the College Common Room and in his clubs as in the class-room and in the Senate chamber.

W. J. E. Jessop

NEWS and VIEWS

Experimental Physics at Liverpool:

Prof. J. M. Cassels, F.R.S.

Prof. J. M. Cassels, who has retired from the chair of physics in the University of Liverpool, joined the staff as a lecturer in 1952. In 1955 he was promoted to senior lecturer and in 1956 was appointed to the professorship of experimental physics which had been instituted a few years before but had remained vacant. He had gone to the Atomic Energy Research Establishment as a research fellow in 1949 on completing his Ph.D. at Cambridge, having previously done some war work there. At Harwell, he joined the research group working on the new 170-MeV. synchrocyclotron and played a leading part in the experimental programme on *p–p* and *n–p* interactions. He transferred to Liverpool to work with the higher energy (380 MeV.) Liverpool cyclotron, which came into full operation at the end of 1954. Largely because of Cassels's foresight, they had a full experimental programme ready to go, and this has continued at a steady pace ever since. Cassels ran a small group of his own, and his name is on many of the laboratory's papers, especially some concerned with pion interactions. But his influence went far beyond his own group, and inspired much of the high-energy work of the laboratory. His strength is both in experimental techniques and in his grasp of theory. He is also an enthusiastic teacher, and a very fine lecturer. He resigned his post to take up, in the autumn of 1959, a visiting professorship in Cornell University, where he will be able to continue his work on high-energy nuclear physics. In 1959 he was elected a Fellow of the Royal Society.

Dr. A. W. Merrison

Dr. Merrison, who has been appointed as Prof. Cassels's successor, was educated at King's College, London, and after taking a degree went to work on centimetric radar at the Signals Research Development Establishment. In 1946 he transferred to the Atomic Energy Research Establishment, Harwell, and worked on various aspects of neutron spectroscopy in the Nuclear Physics Division. He was appointed as lecturer in the University of Liverpool in 1951 and transferred to the research appointment known as the Leverhulme lectureship in 1954. He became a group leader on work with the large 380 MeV. synchrocyclotron and published several important papers on pion physics. In the spring of 1957 he was appointed to a staff post at CERN, the international high-energy laboratory at Geneva. There he worked with the 680-MeV. synchrocyclotron which started work shortly after. One of the results of his team, the discovery of the rare mode of decay of a pion directly into an electron instead of through the normal muon, is considered as of exceptional importance in confirming the theorists' general conception of these particles. Recently, Merrison has been concerned with arranging work for the 28-GeV. proton synchrotron at CERN which has just started working. Dr. Merrison had no opportunity of taking a normal Ph.D. course in a university on account of the War, and so took his degree as a member of the University of Liverpool staff. He is expected to return to the University in the autumn of this year.

Geological Survey and Museum:

Sir William Pugh, O.B.E., F.R.S.

Sir William Pugh, director of the Geological Survey of Great Britain and the Museum of Practical Geology, is retiring at the end of July. Sir William, who was born on July 28, 1892, was educated at the County School, Welshpool, and at the University College of Wales, Aberystwyth. After service in the First World War, in which he was made O.B.E. (Military Division), received the French Croix de Guerre and was twice mentioned in dispatches, he was appointed in 1919 professor of geology at Aberystwyth. In 1931 he was appointed to the chair of geology in the University of Manchester, and became pro-vice-chancellor and later deputy vice-chancellor of that University. He was awarded the Murchison Medal of the Geological Society in 1952 for his researches into the stratigraphy of the Palæozoic rocks in Central Wales. Sir William became director of the Geological Survey and Museum in 1950. He was elected a Fellow of the Royal Society in 1951, and knighted in 1956.

Dr. Cyril J. Stubblefield, F.R.S.

Dr. Cyril J. Stubblefield is to succeed Sir William Pugh as director of the Geological Survey of Great Britain and the Museum of Practical Geology. Dr. Stubblefield was educated at the Perse School, Chelsea Polytechnic and the Royal College of Science, London. In 1923 he was appointed demonstrator in geology in the Imperial College of Science and Technology, a post he occupied until 1928, when he joined the Geological Survey as a geologist. In 1929 he entered the Department of Palæontology of the Survey; and in 1947 he was appointed chief palæontologist. This post he held until 1953, when he was promoted to an assistant directorship in charge of Special Services, and Northern Ireland. Dr. Stubblefield has made many important contributions to our knowledge of the palæontology and stratigraphy of the Palæozoic rocks, and in particular has made a special study of the trilobites. His contributions to geological science have received recognition from the Geological Society of London, by the award of the Bigsby Medal in 1941, and, in 1955, the Murchison Medal. He was elected to the Royal Society in 1944. Dr. Stubblefield's geological activities have not been restricted to his work on the Geological Survey, for he has been an active member of various scientific societies. He is at present president of the Geological Society of London, vice-president of the Palæontographical Society, and a member of the Council of the British Association.

Willis Rodney Whiting Award : Dr. Morris Cohen

Dr. Morris Cohen, of the National Research Council, Ottawa, is to be awarded the Willis Rodney Whiting Award for outstanding work on corrosion. The presentation will be made in Dallas, Texas, on March 14 by the U.S. National Association of Corrosion Engineers. Dr. Cohen is head of the Corrosion Group in the Division of Applied Chemistry, Canadian National Research Council. His work has been largely in physical chemistry, finding what forms corrosion takes, identifying corrosion products, determining rates of corrosion in pure metals and metal alloys. The investigations have included the polishing, etching and electroplating of metal surfaces in order to study the effects of such treatment on the resistance of the metals. Dr. Cohen was born at Regina in 1915, received his B.A. degree at Brandon College in 1934, and his M.A. and Ph.D. degrees at the University of Toronto. He joined the staff of the National Research Council in 1943.

U.S. Navy's Bathyscaphe *Trieste*

On January 24 the U.S. Navy's bathyscaphe *Trieste* successfully dived to a depth of 37,800 ft. in the Pacific Ocean. The region selected for the dive was the Marianas Trench, the depth of which had previously been estimated at 5,364 fathoms (32,184 ft.). Pressure measurements on the bathyscaphe reached 16,883 lb. per sq. in. during the half-hour stay on the ocean floor. The total descent was accomplished in 4 hr. 42 min., and the ascent in 3 hr. 17 min. The operation was directed by M. Jacques Piccard and Lieut. Don Walsh.

New Research Qualification

The Royal Institute of Chemistry has established a Research Diploma for work in pure or applied chemistry to be awarded to graduate members, associates or Fellows of the Institute under conditions similar to those for the Ph.D. degree of a university. The Research Diploma will be particularly directed to those who are unable to satisfy the requirements for taking a higher degree of a university, but who may be able to undertake research under an approved supervisor in a technical college, an industrial firm, a Government department or a research association. The scheme will apply equally to university graduates and those who qualified at technical colleges. Further information can be obtained from the Assistant Registrar, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

International Computer Federation

Eleven nations have now ratified the status of the newly-formed International Computer Federation. The Federation was formed following the first international conference on Information Processing, sponsored by Unesco and held in Paris during June 1959. At a provisional committee for the Federation the following members were named : *Chairman*, Isaac L. Auerbach (United States) ; *Vice-chairman*, Prof. A. A. Dorodnicyn (U.S.S.R.) and A. van Wijngaarden (Netherlands) ; and *Secretary*, J. A. Mussard (Unesco). It is expected that the first meeting of the Council of the Federation will take place later this year, resulting in plans for a second international conference on information processing, with an associated technical exhibit in 1963. Representation of the United Kingdom is by the British Computer Society, Ltd., Finsbury Court, Finsbury Pavement, London, E.C.2, from which further information can be obtained.

First All-India Congress of Zoology

At the first All-India Congress of Zoology, sponsored by the Zoological Society of India and held at the University of Jabalpur during October 24–28, the president, Dr. M. L. Roonwal, director of the Zoological Survey of India, referred in his address to the great number of species comprising the fauna of India and pointed out how little is known of the biology of many of even the commoner ones. He also directed attention to the rapidly decreasing numbers of some of the larger animals and appealed for more effort in conservation. Turning to field ecology, he emphasized what a wide field is available for research which can be done with the aid of a microscope and quite simple equipment. He added, however, that what the worker has to create for himself is a suitable mental atmosphere which will enable him to do hard, arduous work, perhaps for years on end, and without thought of rushing into print too soon merely to increase the number of his published papers. Dr. Roonwal concluded with a plea for the training of more systematists to work on the national zoological collections in the charge of the Zoological Survey of India. The Congress which followed was divided into six sections at which more than a hundred papers were presented, and symposia on marine zoology and fishes in the Indian Ocean and on the re-orientation of teaching of zoology in India were held.

The Coryndon Memorial Museum, Nairobi

Despite the fact that Dr. L. S. B. Leakey, curator of the Coryndon Memorial Museum, has been heavily engaged with work on the Olduvai human remains and lectures in Britain and elsewhere, steady progress is recorded in the annual report for 1958. Probably the two most important exhibits during the year were the Shakespeare Second Folio and living examples of rare snakes. The former is placed in a special case and pages are turned periodically. The live snakes form a major attraction and included gaboon viper, rhinoceros horned viper, boomelang, garter snake and the rare Storms' water cobra. Another exhibit was that of the striped weasel which is only the second to be recorded in Kenya. With the giant human teeth from Olduvai and a Chellean I stage of culture, an ivory tool from the Chellean II level and some samples of red-ochre used by hand-axe man are shown. It is interesting to note that a new method of skinning small mammals has been devised, and a paper on the process is in course of preparation.

Palæoliths at Leopoldville

H. van Moorsel, keeper of the prehistoric and geological collections at the Lovanium University at Leopoldville, has published an article in the Faculty of Sciences on the palæolithic finds in the neighbourhood of the city. There is a vast stony plain in the vicinity which seemingly is very ancient, as it does not appear to have any connexion with the existing river terrace systems. Archæological finds have been few in number, but the author claims to have recognized Sangoan and Middle Stone Age tools. It is difficult to judge from reproductions of photographs and possibly some of the suggested tools figured are really naturally fractured, but there is no reason to think that these cultures were not represented. The article was read as a paper at the fifth Congress of Prehistoric and Protohistoric Sciences at Hamburg in 1958.

Central Electricity Generating Board Research Fellowship

The Central Electricity Generating Board is offering a research fellowship, tenable at St. Catherine's College, University of Oxford, in the physical sciences, including metallurgy, engineering or mathematics. The fellowship, tenable for three years, will take effect from October and will be valued at £1,000 per annum. It is open to persons of British nationality, who by the date of his or her appointment have taken the degree of doctor of philosophy or gained the equivalent experience in research. Applications should reach the Master elect, St. Catherine's College Planning Office, 42 Banbury Road, Oxford, not later than March 31.

Refresher Course on Science in Schools

The Department of Extra-Mural Studies and Education of the University of Durham, King's College, Newcastle, is organizing, in conjunction with the North-Eastern Association of the British Federation of University Women, a refresher course on Science in Schools. The course is intended primarily for women with scientific training who, having had to interrupt their careers, now wish to take up or return to teaching in schools. The course will take place at the University during March 23–30. Further information can be obtained from Miss C. Cruse, 292 Ovington Grove, Newcastle upon Tyne, 5.

University News : Belfast

The following appointments are announced : Dr. D. J. Carr (Melbourne), to the chair of botany ; Dr. R. A. Henstock, to be senior lecturer in pure mathematics ; and Dr. A. L. Stewart, to be lecturer in applied mathematics.

Monash

The following first appointments of staff at Monash University, the newly established University in Victoria, Australia, are announced : professor of biology, Dr. A. J. Marshall, reader in zoology and comparative anatomy at St. Bartholomew's Hospital Medical College, London ; and professor of chemistry, Dr. R. D. Brown, senior lecturer in general chemistry, University of Melbourne.

Announcements

Sir Patrick Linstead, rector of the Imperial College of Science and Technology, University of London, has been appointed chairman of the Science Advisory Committee of the British Council and a member of the Executive Committee of the Council in succession to the late Sir Alfred Egerton.

Sir Harold Roxbee Cox, vice-chairman of the National Council for Technological Awards, has been appointed chairman in succession to Lord Hives, who has retired. Sir Harold Roxbee Cox, formerly chief scientist, Ministry of Fuel and Power, is deputy chairman and chairman-elect of the Metal Box Co., Ltd., and a director of Wilmot Breedon (Holdings), Ltd., and of Boulton Paul Aircraft, Ltd. ; he is a member of the Council for Scientific and Industrial Research.

The Scottish Branch of Aslib is organizing its annual general business meeting and a one-day conference to be held on February 5 in the Scottish Central Library, Lawnmarket, Edinburgh. Further information can be obtained from Miss N. I. Shinie, T. and H. Smith, Ltd., Edinburgh 11.

The twelfth international symposium on Crop Protection is to be held at the Agricultural College of the University of Ghent on April 26. The symposium will coincide with the twenty-fourth five-yearly international Floralia of Ghent. Further details can be obtained from Prof. J. van den Brande, State Agricultural College, Ghent, Belgium.

The joint annual meetings of the Chemical Society and the Royal Institute of Chemistry will be held in Belfast during April 5–8 at the David Keir Building of Queen's University, Belfast. Further details can be obtained from the Joint Annual Meetings Officer, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

The spring meeting of the Clay Minerals Group of the Mineralogical Society will be held during April 12–13 in the Department of Chemistry at the University of Aberdeen. The topic for discussion will be "Clay Minerals in Sediments". Further details can be obtained from Dr. R. M. S. Perrin, School of Agriculture, University of Cambridge.

Three courses of six lectures each will be given at the Borough Polytechnic, Borough Road, London, S.E.1, on the following topics : Variety Reduction in Engineering (commencing on February 17) ; Lubrication and Lubricants (commencing on February 22) ; Foundry Sands (commencing on February 9). Further information can be obtained from the Secretary of the Polytechnic.

The Association of Oil and Colour Chemists has announced that the twelfth Technical Exhibition will be held at the Royal Horticultural Society's New Hall, Greycoat and Elverton Streets, London, S.W.1, during March 15–17. Further details can be obtained from the secretary, Mr. R. H. Hamblin, Association of Oil and Colour Chemists, Wax Chancellor's Hall, Gresham Hall, London, E.C.2.

Prof. A. Masevich, vice-president of the Astronomical Council, U.S.S.R. Academy of Sciences, Moscow, is to give a number of lectures throughout Great Britain on "Conquest of Space". These lectures are being organized by the Society for Cultural Relations with the U.S.S.R. at the Royal Festival Hall, London, February 6 ; Birmingham Town Hall, February 8 ; Colston Hall, Bristol, February 9 ; and the Free Trade Hall, Manchester, February 12. Tickets are available from the agents of the various halls.

SHELL DEPARTMENT OF CHEMICAL ENGINEERING, CAMBRIDGE

IN March 1945 the University of Cambridge gratefully accepted the offer of the Shell Group of Oil Companies to found a School of Chemical Engineering. This generous gift amounted to £435,400 and was accompanied by an offer to make an annual sum of £2,500 (later increased to £3,000) available until further notice, thereby forming the Shell Chemical Engineering Studies Fund.

The first Shell professor of chemical engineering, T. R. C. Fox, took up his appointment in October 1946 and teaching started in October 1948. Since that time 187 students have graduated in chemical engineering and the teaching staff has grown to its present establishment of six lecturers, three demonstrators and an assistant director of research (two of these posts are vacant at present).

The teaching in the Department consists of a two-year course taken either after Part 1 of the Natural Sciences Tripos or Part 1 of the Mechanical Sciences Tripos. This course leads to the Chemical Engineering Tripos, normally taken in the fourth year. From the outset it has been the aim of the Department to provide a scientifically based training both for those who have been led to the subject through their interest in chemistry and for those whose primary training has been in engineering. It is not the intention to mould these two groups into a single pattern but rather to modify both and let them temper one another. In this way the Department has pioneered a new development in chemical engineering education.

Graduates in chemistry or engineering from other universities may also be admitted to the course, which qualifies them for the B.A. degree.

In the early days the Department was housed in a temporary single-storey building in Tennis Court Road; eventually 9,000 sq. ft. of temporary accommodation was provided on this site. After the exploration of many alternative schemes, a permanent site adjacent to the Cavendish, Metallurgy and Zoology Laboratories was allocated in 1955. Mr. J. Murray Easton was appointed architect and a building with a net floor area of 22,000 sq. ft. was designed to replace and incorporate parts of the old chemical laboratory. Work on the building started in November 1956 and the Department began to move into the first section of its new building early in 1959. The main group of laboratories was opened by Lord Godber, chairman of the Shell Group of Companies, on December 9, 1959 (Fig. 1).

The Laboratories of the Department are partly in a new steel-framed building of five floors and partly in the four-storey building along the Pembroke Street frontage, originally built in 1907, which has been virtually rebuilt internally. The last stage of the rehabilitation of the 1907 building (the ground floor now occupied by the Chemistry Laboratory) will begin in June 1960. The two buildings have been welded into a whole by a new staircase which feeds floors in the converted building from half landings.

The basic design envisaged relatively large-scale experiments being carried out at the lowest level (in what the Department terms the Unit Operations Laboratory (Fig. 2), which is 48 ft. × 45 ft. × 22 ft. high) with adjacent service workshops, stores and instrument laboratory. On the first floor are centred the teaching activities with lecture rooms, library, chemical laboratory and cloakroom. On the second and third floors are eleven combined office-research laboratories for teaching staff, five small research laboratories and one large research laboratory for chemical bench work. Existing structural and service limitations restricted the use of the converted 1907 building. A bank of six constant-temperature rooms (four having 16–17 ft. headroom) are built in the region of the junction between the two buildings, and on the first floor advantage was taken of the headroom to provide a ramped lecture theatre capable of seating both first- and second-year classes together. The basement is used for stores and mechanical services and a new roof structure was built to provide a drawing office and common-room in place of a group of attics at various levels.

In the Unit Operations Laboratory which passes through two floors there are galleries to permit access to apparatus at 4 ft. and 11 ft. above floor-level. There is also a central well 5 ft. deep and provision in five places to pass through the floor of the laboratory above, so increasing the effective ceiling height at these points from 22 ft. to 35 ft.

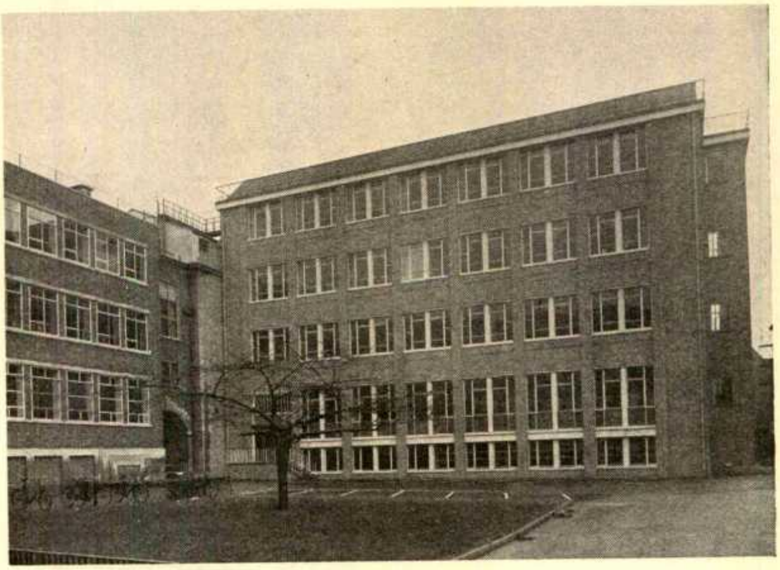

Fig. 1. New building for the Department of Chemical Engineering, Cambridge

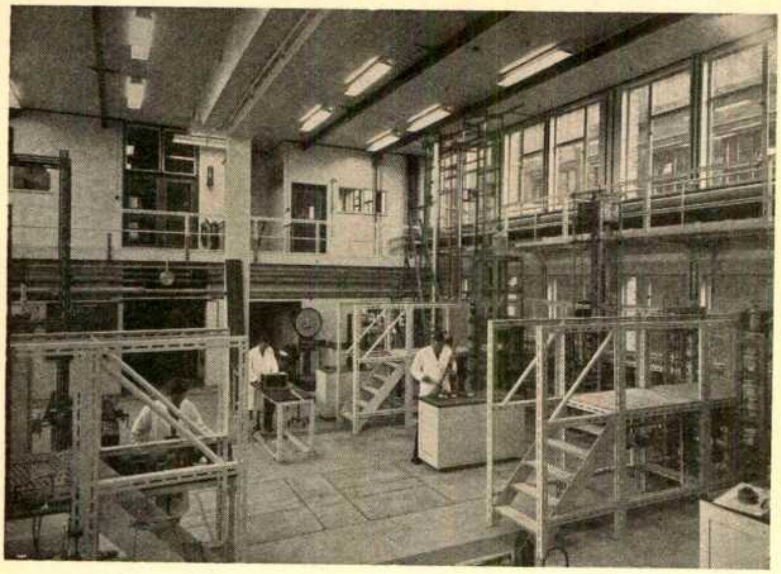

Fig. 2. Unit Operations Laboratory

Each experimental position in the laboratory has steam (10 and 100 lb./sq. in.), compressed air (10 and 100 lb./sq. in.), gas, water and electrical (60 amp.) services. These services are provided by: (1) two steam ring mains operating at variable pressures and supplied by three boilers with a combined capacity of 2,500 lb./hr.; (2) two compressed air ring mains (one 5 in. in diameter for part of its length) operating at variable pressures up to 100 lb./sq. in. and supplied by four reciprocating compressors providing up to 540 c.f.m.; (3) two water ring mains fed from a 6,000 gal. capacity tank in the roof. In the case of both air and steam there is a cross-over pipe network to permit any compressor or boiler to feed either of the pair of ring mains. Additionally there is a general ventilation extract system, balanced by a warmed air intake, and there is also a furnace extract system.

Fume cupboards in the research laboratories have been installed in the centre of the building in spaces between ducts. The fume cupboards are of the 'walk in' type and as the tray at bench height is removable they may be used for high towers and similar apparatus. They are finished internally with an epoxy resin. The cupboards are arranged in vertical banks of three, each bank being exhausted by a single fan. Two of these banks have interconnecting, lined trunking to permit the installation of apparatus approximately 6 in. × 12 in. through three floors, that is to say, approximately 40 ft. high in what becomes effectively a single fume cupboard. Provision has also been made to install apparatus if required in ducts (5 ft. 6 in. × 3 ft. 6 in.) which run almost the full height of the building. These ducts are now fitted with removable floors and used as cupboards.

In the earlier years of the Department's existence, research work necessarily took second place to the development of the teaching programme. However, its importance has steadily increased, and to date twenty-one research students have submitted work for research degrees.

A feature of the Tripos course is that students carry out a modest research project during their final year, rather than a formal laboratory course in chemical engineering operations. Some information of genuine value has been obtained.

The industries or other fields of employment entered by graduates on leaving are as follows:

Petroleum and petrochemicals	29
Chemicals (excluding petrochemicals)	80
Chemical plant manufacture	21
Atomic energy	23
Miscellaneous	34

The original staff of the department is now widely dispersed. Prof. K. G. Denbigh was the first professor of chemical technology at Edinburgh, Prof. E. S. Sellers became the first professor of chemical engineering at Swansea, Prof. J. M. Kay is at the Imperial College, London, and Prof. P. V. Danckwerts has recently returned from the Imperial College to take up the Shell professorship following the resignation of Prof. T. R. C. Fox, who is to continue teaching work in Cambridge in the Engineering Laboratory.

THE SCIENCE MASTERS' ASSOCIATION

NEARLY seven hundred science teachers from many parts of the British Isles gathered for the annual meeting of the Science Masters' Association, which was held in the University of Southampton during December 29, 1959–January 1, 1960.

There was a large attendance at the Guildhall on the evening of December 29, when members of the Association were welcomed to Southampton by the Mayor, Mrs. R. M. Stonehouse. The civic reception was followed by a lecture, illustrated in colour, on "Southampton Borough Archives" by the Borough archivist, Mr. Bruce Jones, and members were able to examine some of the historic treasures of Southampton, which were displayed with models and illustrations of modern educational buildings prepared by the Borough architect, Mr. L. Berger.

The programme included lectures and demonstrations, visits, discussions, films and, in addition to the usual members', manufacturers' and publishers' exhibitions, a number of special exhibitions which attracted considerable interest.

The morning sessions were devoted to lectures and discussions which fully maintained the high standards of the annual meeting. Of special interest to physicists were the lectures by Prof. A. M. Taylor on "Some Demonstrations in Light and Colour" (which filled the large physics lecture theatre to overflowing on two successive mornings), Mr. S. Weintroub on "The Solid State", Mr. B. H. Venning on "Analogue Computers and their Use as a Teaching Aid", and Mr. E. Wolfendale on "The Junction Transistor and its Application". Chemists enjoyed lectures by Dr. G. W. A. Fowles on "Directed Valency" and Dr. H. M. Frey on "Reactions of 'Hot' Molecules", while the interests of biologists were stimulated by lectures by Prof. W. T. Williams on "The Applications of the Pegasus Digital Computer to the Solution of Problems in Plant Ecology and Taxonomy", by Dr. K. A. Munday on "Modern Developments in the Use of Cooling in Physiological and Biochemical Studies", and by Mr. T. H. Blank on "Research on Game Birds". Many teachers found pleasure and profit in lectures not immediately connected with their own branches of science, notably in hearing Prof. E. J. Richards on "Some New Problems in Aeronautical Research", Dr. N. S. Grassam on "Nuclear Engineering—Past, Present and Future", and Dr. K. Hecht on "Atomic Physics in West German Schools".

A most interesting programme was arranged for afternoon visits to industrial establishments, various departments of the University, and places of general interest. The traditional exhibitions were well supported; the sixty manufacturing firms represented had put on a fine display and reported exceptionally keen interest in their products, while there was a steady stream of members to see the excellent publishers' stands in the pleasant setting of the Lanchester Engineering Building. The members' exhibition, always a popular focal point at the annual meeting, and housed this year in three laboratories in the Department of Physics, showed all the usual fertile ingenuity and craftsmanship that is an object lesson and a stimulus to those who are not so skilful or so inventive.

An important feature of the meeting was the special exhibition on "Atomic and Molecular Structure and Nuclear Energy", with some fine displays on this theme by firms and other organizations in the United Kingdom, the United States and West Germany. These included a student reactor which employs natural uranium fuel with a light-water moderator and a small polonium–beryllium neutron source, a reactor simulator and monitoring equipment, and many pieces of apparatus and teaching aids which would be valuable to schools, technical institutions and universities. Equipment from America included a micro-wave analogue of the Bragg diffraction apparatus, using aluminium balls to simulate the crystal lattice structure, an ingenious α-particle counter, and a neat apparatus for the determination of Planck's constant. There was an impressive display of equipment which is available for the teaching of atomic physics in West German schools. Other special exhibitions included visual aids, a feature display on textile research, and apparatus and teaching aids contributed by teachers in secondary modern schools.

During the meeting simultaneous discussions took place on draft syllabuses in physics, chemistry and biology, prepared by subject panels set up by the Association to implement the policy statement, "Science and Education", which was published in 1957. A fourth panel is working on a syllabus for education in science as part of general studies in the sixth form.

A most enjoyable discussion by the Science and Religion Group of the Association was initiated by Dr. Donald MacKay, of King's College, London, who took as his theme "The Christian Doctrine of Man".

A real highlight of the Southampton meeting was touched on Wednesday evening, when Dr. D. G. James, vice-chancellor of the University, gave his presidential address to a packed audience in the refectory of the University, following the Association dinner and University reception. Dr. James, speaking on the subject of "Literature and Science", emphasized the imperative need to bring the sciences and the humanities together in education; calling for more intellectual excitement and the necessity to look beyond one's own special interests to try to see them in relation to others and to the abiding questions, he concluded: "It cannot be doubted that, as boys and girls in ever-increasing thousands move on to the sixth form and the universities, the enjoyment of literature and the arts by the majority who will read science may not be sacrificed except at a severe cost. At the same time, it is clear that the life of science shares with the arts the power of the creative imagination, and that fellowship of the scientist and the artist, instead of being, if Sir Charles Snow is right, a rare thing, should be the most natural thing in the world".

The marked growth of the Association in membership and in its links with other organizations was a major topic at the business meeting on December 31.

From a membership of 2,700 in 1945, the number had grown to 4,500 in 1955 and is now 6,500, the growth continuing at a steadily increasing rate. This rapid development has thrown an increasing burden on the officers of the Association, and the chairman, Dr. H. F. Boulind, emphasized the urgent need for a permanent headquarters with salaried staff to enable the work of the Association to be carried on effectively.

Regarding the links of the Association with other bodies, it was pointed out that, with the growing realization of the significance of science in education and the consequent activity by many organizations and individuals, there was bound to be some duplication of effort through ignorance of what others were doing, some waste of resources and some inefficiency. This indicated an urgent need for a co-ordination centre as a home for science education. This would at least reduce some of the overlapping and wasteful use of personal and financial resources; more positively, this venture could have a really valuable effect on science education not only in Britain but also more widely, for example, through Unesco and the Organization for European Economic Co-operation, through associations of science teachers in other countries and through individuals using the Centre. The Association already has many valuable links with other organizations both in Britain and abroad; others are being forged, and the meeting was very glad to welcome Prof. H. F. Meiners, of New York, who had come to Southampton to discuss the extension of the happy co-operation between the Association and the American Association of Physics Teachers. The Science Masters' Association is sponsoring the establishment of the proposed Science Education Centre in January 1960 as one way of celebrating the diamond jubilee of its foundation. The Centre is being set up temporarily at Holt, in Norfolk, but it is hoped that sufficient financial and other resources will be put at the disposal of the Association to provide more adequate accommodation and equipment in a less-remote spot in the near future.

H. Lockett

ECOLOGY OF PARASITES

THE autumn meeting of the Parasitology Group (Institute of Biology) was held in London at Birkbeck College on October 30, 1959. In the opening discussion of the meeting, which was entitled "The Ecology of Parasites", Prof. B. G. Peters (Imperial College, London) considered the effect of soil factors on plant parasitic nematodes. Soil-living stages are directly influenced by edaphic factors such as moisture, temperature, chemical constitution of the soil and the presence of predators and of possible hosts. Prof. Peters went on to point out that in the parasitic phases, complex relationships exist between the biomasses of host plants and parasitic eelworms. With increasing plant nutrients in the soil there is an increase in host biomass and a correlated increase in parasite biomass. However, at a fixed nutrient-level, the correlation between host and parasite biomasses is negative and the parasites retard the development of their hosts. In species of *Heterodera* having one generation each season, the multiplication rate is highest at low population-levels. As the parasite population density builds up so the rate of multiplication falls. Concurrently, the host at a fixed population density shows a correlated fall in biomass until it can barely maintain the eelworm population. Under these conditions, catastrophic crop losses occur in one season and can alternate with reasonable crop yields the next.

Dr. R. Lainson (London School of Hygiene and Tropical Medicine) spoke about the adaptations shown by coccidial parasites to their environment. The life-histories of sporozoan Protozoa show striking modifications which may be regarded as allowing the parasite to overcome the hazards of transmission and which form an evolutionary pattern, often serving as a basis of classification.

Eimeria, a typical coccidian, has one host in its life-cycle and the difficulties of transfer are overcome by the production of resistant oocysts, which can remain viable outside the host for long periods. The hæmogregarines have eliminated the dangers of a free-living stage and are passively transferred by ectoparasitic invertebrates such as leeches, ticks and mites. The parasites circulating in the blood cells of the vertebrate are ingested by a blood-feeding invertebrate, which itself is eaten by a new vertebrate host.

Yet other coccidians are further adapted and undergo most of their life-cycle in the ectoparasite, the vertebrate virtually serving as a reservoir of infection for the invertebrate host. Besides these modifications in the mechanism of transmission, changes have taken place in the processes of fertilization and sporogony, and all these adaptations ensure maximum efficiency in the maintenance and dissemination of the species.

Dr. S. D. Garrett (Botany School, Cambridge) discussed inoculum potential. Infectivity denotes the potentiality for infection of a single infective organism. In order to produce disease in 50 per cent of inoculated host individuals a large dose of infective agents is often required, and the term 'inoculum potential' denotes the infection potential of this dose. The necessity for the large dose in establishing infection can be explained either by the low probability for infection by a single organism, the hypothesis of independent action, or by the necessity for synergic action between individual infective organisms—the hypothesis of synergistic action.

Evidence available from plant pathology supports that from animal pathogens and accords better with the hypothesis of independent action. However, the possibility still exists that synergism may be involved in the production of disease in an 'unnatural' host, for example, where it is necessary to apply heavy doses of rust fungus spores to the leaf surface to produce disease. The chief evidence of synergistic action is provided by experiments with fungi infecting the roots of trees. The high resistance of the roots can only be overcome by a fungal inoculum provided with a food base, and infection is accomplished by mycelial strands and not by individual hyphæ.

Dr. G. Salt (King's College, Cambridge) spoke about the environment of larval parasitoid insects. The ecology of these parasitoids has two distinct aspects. The adults are free-living, usually winged, and the ways in which the females select the hosts and parasitize them have been widely studied. However, the ecology of the parasitoid egg or larva living on or in a particular host has received relatively little attention. Dr. Salt described some of his work on the life-history of a parasitoid larva within the hæmocœl of its larval insect host and gave an account of the environment, the changes which must occur in it if the parasite is to survive and the interactions between host and larva. An 'unnatural' host reacts to the presence of the larva in its hæmocœl, the larva becoming surrounded by an envelope of host blood which prevents development.

Dr. D. Arthur (King's College, London) described the ways in which ticks select their hosts and the feeding sites upon them. Hard ticks, on the tips of vegetation, are aroused to a state of preparedness by non-directional, tactile stimuli. These stimuli are reinforced by interacting odour and temperature stimuli prior to attachment to the host. In soft ticks, temperature appears to be the dominant stimulus for attachment.

The range of hosts selected by the parasite is not precisely known because of incorrect identification of ticks by earlier workers. However, the majority of ticks appear to be non-specific in their host selection. Some are limited to certain groups of hosts, but very few are specific to one host species, even among primitive ticks feeding on primitive mammals and the more advanced forms such as those found exclusively on Primates. For example, *Ornithodorus moubata* appears in three biological forms, that found on warthogs, porcupines and ant-bears possibly being primitive. The sites of attachment of various species and the reasons for their selection were discussed.

The chairman, Dr. E. L. Taylor (Veterinary Laboratory, Weybridge), opened the discussion. The adaptations of a parasite show various aspects operating simultaneously. The ecology of stages outside the host is similar to that for free-living organisms, but the parasite has also to find its host, effect an entrance or attachment and then behave in a way that ensures its own and its host's continued existence. The effect of parasite on host has been widely studied, but the effect of the host on the parasite should also be considered. Indeed, the two physiologies are interacting and in some circumstances mutual benefit may accrue. Contrary to the usual tenet of successful parasitism, the parasitoid insect larva kills its host, and Dr. Salt commented that the percentage of host population infected was small and losses, which could be considered as due to a refined form of predation, could easily be supported. Dr. Hindle cited examples of the extinction of host species by parasitism. Immunity reactions of the host, although prejudicial to an individual parasite, operate for the benefit of the species by limiting the parasite population. This mechanism is different in plant and animal hosts, and Dr. Jones said that plants do not show immune reactions, but rather a resistance to infestation which is a property of the individual cells. Parasite populations of plants show both density-dependent effects and independent factors, such as the steady rate of decay of the population of cyst-forming eelworms in the soil.

Immunity in invertebrates has been little studied, but there appears to be no true immunity although the production of non-specific antibodies may be evoked by the introduction of any foreign object. When the parasitoid insect larva with its envelope of host blood is transferred to another similar host there is no homograft reaction such as occurs in vertebrates.

Dr. Garrett suggested that another important difference between the plant and animal host is that in the plant there is always a region of young tissue at the growing points, whereas in animals growth usually ceases at maturity. Young animals are more susceptible than adults, and in plants the rootlets, for example, are more susceptible than the roots, the resistance of which can only be overcome by the most specialized of parasites. This phenomenon of age-resistance also operates in favour of the parasite by limiting the population.

The proceedings of this meeting will not be published in full. JUNE MAHON

ORIGIN OF TEKTITES

By DR. GEORGE BAKER

Commonwealth Scientific and Industrial Research Organization, Mineragraphic Investigations,
c/o University of Melbourne, Parkville, N.2, Victoria

CERTAIN aspects of recently advanced concepts relating to the origin of tektites require some considerable modification in the light of the conclusions arising from long-continued and detailed studies of the tektites from Australia. So far as is known, australites are the most recently arrived tektites on the Earth, and have evidently not lain upon the Earth's surface for more than 5,000 years. Furthermore, in terms of preservation of original shape types modified by secondary phenomena generated during rapid transit through the Earth's atmosphere, they are unmatched by any tektites from any other strewn-field on the Earth. Consequently, they are in the best condition on which to base conclusions as to their origin. Moreover, the very best preserved, most perfectly developed australites, which come from the Port Campbell district on the southern coast of Western Victoria, are retained in Australia, and have not been critically examined by overseas writers who make reference to australites in their publications.

Much detailed information has now accrued relating to the primary shapes, the secondarily modified shapes arising from the action of aerodynamical phenomena during ultra-supersonic and supersonic flight through the Earth's atmosphere, and the effects of tertiary phenomena such as subaerial erosion resulting from 5,000 years exposure to atmospheric agents. Considerable and detailed studies of the specific gravity of the same and different types of shape from the same and from different localities have been carried out. Many refractive index determinations have been made and specific refractivities calculated. Arcs and radii of curvature of remnant primary (posterior) and newly formed secondary (anterior) surfaces have been determined graphically from silhouette tracings, and significant conclusions drawn from these. Several etch solution tests have been conducted which provide valuable information of the effects of natural etching upon original structural elements and sculpture patterns of australites. Three more chemical analyses have been made and the composition related to specific gravity and refractive index values. The effects of heating to 1,200° C. has added further knowledge to the australite problem generally.

Studies of Darwin glass, 'straw-silica glass' and other non-volcanic terrestrial glasses have led to the rejection of Darwin glass from the group of the true tektites. Thin-section studies of the internal schlieren of australites have clarified the relationships between the core or body portion and the circumferential flange. All the structures, sculpture patterns and present shapes of australites can be adequately explained in terms of the few primary forms developed in an extraterrestrial environment, and subsequent modification by aerodynamical phenomena during high-speed earthward flight through the Earth's atmosphere, with a further modification by fragmentation, abrasion and solution-etching of the shapes so developed.

The results of these and other detailed studies have appeared during the past two decades[1].

The question of the origin of australites is admittedly still unsolved, but the weight of evidence from Australian studies is strongly in favour of an extraterrestrial source.

The concept has recently been advanced[2] that the arrival of tektites from space, with the distribution found on Earth, is not possible. Urey has calculated that if australites arrived as a swarm, its mean density must have been greater than 10^{-6} gm. cm.^{3}, its diameter some 10^{8} cm., and hence there would be a piling up of australites to a depth of 100 gm. cm.$^{-2}$ over southern Australia. Urey further states that he knows no answer to this problem. Assuming that the mean density and diameter of the swarm of australites are those given by Urey, detailed studies of australites and their distribution immediately supply the answer to the problem of their piling up to the depth suggested. As Urey states, this piling up is certainly "not the case". In fact, such a piling up to the depth calculated never could occur, for three very significant processes have operated to prevent it. The first and most important process operated for a very short period of time, but was, indeed, most effective in reducing the bulk of the swarm. The australites provide all the necessary evidence to show that they entered the Earth's atmosphere as small, cold (and hence solid) bodies with pre-formed primary shapes and pre-determined sculpture patterns, and that during high-speed transit through the atmosphere, in a matter of minutes at most, many of these forms were reduced in bulk by up to and more than 65 per cent, some by up to 80 per cent. This arose from the development of shock waves causing high pressures and temperatures, the generation of laminar boundary layer flow and reversed boundary layer flow leading to fusion stripping and ablation of the leading surfaces of the australites, and consequently considerable reduction in the size of each original form. Here, then, is an excellent means of reducing the estimated figure of a piling up process by two-thirds and more, and the amount lost in this way must be even greater when it is considered that an untold number of smaller original forms (less than 0·5 cm. in diameter) were undoubtedly completely consumed during atmospheric flight, as evidenced by studies of the smallest complete forms that survived the processes of ablation and thin-film fusion-stripping.

Urey has expressed surprise that a small glass object 1–2 cm. in diameter would travel at high velocity through the atmosphere, keeping one orientation as is necessary in the case of the more button-shaped tektites. Nevertheless, australites have done just this, and, moreover, not the "more button-shaped" examples alone, but also the ovals, boats, dumbbells, teardrops and canoes, etc., the better preserved examples of which all reveal identical types of secondarily developed structures and features (for example, circumferential flanges, concentric flow-ridges, clockwise spiral flow-ridges, anticlockwise spiral flow-ridges, radial flow-lines on the anterior surfaces, and so on). The role of aerodynamical phenomena at high speeds of flight supplies the answer to the development of all these features, and nearly all the australites bear testimony to the maintenance of a steady state of airflow, a state that can only be achieved during supersonic (and ultrasupersonic) speeds of atmospheric flight, with translatory forward motion only, and neither rotation about a polar axis, nor overturning during flight. As long as supersonic airflow obtains, a state of steady flight is maintained; but evidence is present on the anterior surfaces of some australites to indicate that although the motion of the objects was definitely limited to one direction, there arose some degree of 'wobbling' as an outcome of form-drag and buffeting at the high speeds that prevailed. Whether any of the australites in the swarm were affected by accidental or overtake collisions, it has not yet been possible to prove.

After australites landed on the Earth's surface, many without fracturing on impact, processes of abrasion and solution-etching played their part throughout the next 5,000 years or so, thus further reducing the mass of many forms. This is confirmed from detailed studies of the curvature – size relationships of excellently preserved australites, taken in conjunction with studies of other australites that reveal a whole range of tertiary modifications by subaerial agencies, from slightly worn and etched shapes that are almost perfect, right through to strongly abraded and/or deeply etched, now incomplete specimens, and all manner of fragments that can be assigned to one or another of the few shape groups, as well as many nondescript fragments. On the whole, australites have not lost anywhere near the amounts of glass by abrasion and etching as have tektites from other strewn-fields in other parts of the world, such as bediasites (which are very much older in terms of the time they have been on earth surface) and rizalites, etc. (which are also older, but also occur in regions subject to more pluvial, tropical conditions). Nevertheless, significant amounts of abrasion and solution-etching have been effective in certain parts of the Australian strewn-field, more especially in the arid regions and marginal lands, as is evident from comparisons between specimens from those regions and specimens in better preserved states from the more temperate regions of the island continent.

However, it is at present impracticable to assess the amount of australite glass lost from abraded specimens or the amount removed in solution by etching, for the whole of the 2 million square mile strewn-field. All that can be said with certainty at present is that the examination of some 20,000 specimens of australites in various states of preservation from various localities within the strewn-field indicates that between 50 per cent and 75 per cent of these have lost some 5–10 per cent of the original form, some by attrition from sand-blasting in certain areas, others from rolling in stream beds, some by solution-etching in certain soils, some by both processes, according to their location in the vast strewn-field. Several specimens of australites that are badly worn or deeply etched have lost 50 per cent or more of the original form. Furthermore, studies of the etching of smaller forms and small fragments lead to the conclusion that an unknown number has been completely destroyed by processes of subaerial erosion.

Current etching experiments with australites reveal that a specimen weighing approximately 2 gm. passes completely into solution in 4 per cent hydrogen fluoride in approximately 1,180 hr. at room temperatures. The rate of solubility was 3–4 mgm./hr. during the initial 300 hr. immersion, falling to less than 0·5 mgm./hr. after 1,000 hr. immersion, at which stage the initial form had been reduced in bulk by approximately 99 per cent. Although soil solutions are expected to be far less potent than 4 per cent hydrogen fluoride, nevertheless such solutions have been operative in varying concentrations and in varying quantities from place to place for some 5,000 years. In the most favourable circumstances, therefore, it is apparent that some australites in the right environment where solution-etching has been prevalent have been much reduced in bulk as a consequence of the removal of soluble ions. That entire forms of australites can have been completely dissolved by such a process is indicated by the 2-gm. weight australite that dissolved in 4 per cent hydrogen fluoride in 1,180 hr. without leaving any insoluble residue whatsoever.

Here, then, is a second important factor responsible for causing australite distribution to appear as it does to-day, and it is thus a significant factor in further reducing Urey's estimate of what the thickness of australites should be on the Earth's surface if entering from outer space as a shower; originally the thickness was somewhat greater than now, but loss by subaerial agents of erosion acting for some 5,000 years has been of considerable importance.

A third factor of possibly lesser importance than the first two, but nevertheless of some significance, affects the present distribution of australites on the surface, and hence, indirectly, the thickness of the australite 'pile up' from place to place. This factor introduces the operation of transporting agents such as streams, birds and aboriginal man. It has been generally accepted in the past that australites are normally found in the places where they originally fell to Earth. This seems to apply in many parts of the strewn-field, but in others there is indisputable evidence of movement by stream action into alluvial tin and alluvial gold deposits, as well as into clay pans and lake beds. I have observed several that have been washed over the edges of steep marine cliffs by surface run-off; these fall into talus cones and beach deposits and are ultimately lost by abrasion or swept out by tides on to the adjoining sea-floor. Others have been observed in stream beds entering the sea at grade, and thus provide a pointer to the fact that many specimens that become washed into water-courses ultimately are carried out on to the sea floor from farther inland.

It is a well-known fact that the Australian emu and the plain turkey utilize australites of suitable shape and dimensions as gizzard stones, and thereby can transport australites over considerable distances, at the same time subjecting them to marked degrees of wear in their function as 'grinder-stones'; these birds have been doing this sort of thing since australites first became available to them on the surface of the Earth, as evidenced by the discovery of gizzard stones with the fossilized remains of their ancestors. Aboriginal man has further added to the problem of present australite distribution, inasmuch as he prized these tektites as objects of magic and mystery, and carried them around on his nomadic journeyings; this is further evidenced by the discovery of australites in ancient aboriginal camps and kitchen middens, and by the fact that some show signs of 'carry polish' while others have been fashioned into crude, small implements.

Such events in the post-atmospheric flight history of australites must undoubtedly be taken into account when considering the initial scatter and thickness of australites in the strewn-field. There is no shadow of doubt that in many places the original distribution was by no means what it is to-day.

Thus, the three factors: (*a*) ablation and fusion stripping of primary forms during ultrasupersonic and supersonic earthward flight through the atmosphere; (*b*) subsequent abrasion, fragmentation and solution etching by subaerial agents; (*c*) the habits and activities of certain native birds and aboriginal man; have all been potent in affecting[1] the amount of australite glass that ultimately reached the Earth's surface, and then[2] in affecting its distribution and thickness on the surface. They all add up to a logical reason for the fact that australites are not now piled up to the calculated thickness of 100 gm. cm.$^{-2}$ if they came in from outer space as a shower, and with this objection to the present known thickness removed, added to the knowledge that australites show all the marks of having been subjected to the action of aerodynamical phenomena at high speeds of earthward flight downwards only through the atmosphere, there should be no really serious objection left to the entry of australites from outer space as a shower. Inasmuch as the other tektites from the other known seven strewn-fields of the Earth are much older, much more abraded or infinitely more affected by solution-etching, and do not reveal the remarkable features possessed by australites, it is at present impossible to extend *in toto* these ideas to explain their origin.

Further to the problem of tektite origin, Urey has set out reasons for regarding the several puzzling features of tektites as being capable of explanation in terms of derivation from cometary collision. In fact, however, the reasons advanced only serve to confuse the issue even more than it has been confused in the past several decades. The same arguments apply against the chances of cometary collision being the cause as arguments already advanced[1] against the much earlier theories such as Spencer's meteorite splash hypothesis[3] and Kahn's contraterrene meteorite impact theory[4].

Fatal to all three theories are the facts that the eight accepted types of true tektites fell to the Earth at widely separated times in late- to post-Mesozoic Earth history, and hence cannot possibly fit into the scheme of one cometary collision every 50 million years. The 50 million year cometary cycle was evidently designed to produce bediasites in the Eocene and australites, etc., in the Pleistocene.

The geological evidence, however, shows that the moldavites are Middle Miocene, the Ivory Coast tektites have been suggested to be late Mesozoic, while the bediasites were found in Pleistocene gravels and said to be derived from the Eocene. There are time-intervals of 10–30 million years between these assigned ages. Later in Earth history, the indomalaysianites are regarded as Middle Pliocene, the javaites as Middle Pleistocene, the rizalites as middle or early part of the Late (? Upper) Pleistocene, while the australites are undoubtedly the youngest of all, and definitely Holocene.

There are time-intervals of 3 or 4 million years between the groups of younger tektites, and time-intervals of 15–20 million years between them and the Miocene moldavites. It is thus apparent that the idea of tektite generation in 50 million year cycles of cometary collision cannot be accepted as it stands. Moreover, such cometary collisions would have to result in the meagre total of 2,000 known bediasites by the Eocene cometary collision, produced from a very restricted part of the Earth's surface, and at the other end of a 50-million year cycle, another cometary collision would be required to produce about 600,000 known australites, rizalites, javaites, billitonites and indomalaysianites spread over thousands of square miles of territories widely separated from one another.

Even abrasion, fragmentation and solution-etching differences between the results of the first cometary collision and the second could scarcely be expected to account for such a discrepancy, and at all events, the big Indomalaysian–Philippines–East Indies–Australian strewn-fields contain tektite types that fell to the Earth at different periods of late Tertiary to Quaternary Earth history. A single cometary collision in the Pleistocene cannot therefore explain the origin of the tektites ranging in age from Middle Pliocene to Holocene in the Far East–Australian region. Such a high-energy explosion as that postulated to have affected so vast an area of the Earth's surface must surely have had greater and more far-reaching effects than the mere production of a few thousand pieces of glass of relatively small size; no such effects have been recognized or postulated.

A further difficulty with such a suggested origin is that the single high-energy explosion would be required to fuse all manner of terrestrial materials of different composition, so as to produce tektite glass of generally similar chemical composition in areas 65° of latitude apart. Even if the cometary collision supplied the energy for fusion, the wide array of superficial terrestrial materials would by no means supply relatively homogeneous tektite glass, even with the postulated fractionation into acid and basic fractions, a process which, in itself, is most difficult to conceive during the upward propulsion of fused Earth material that afterwards re-entered Earth's atmosphere according to the cometary collision theory. There should, moreover, be a whole range of partially fused materials formed at each milieu affected by the cometary collision; there should also be a whole range of different kinds of glass irrespective of the postulated acid and basic glasses; there should be removal of the basic glasses (or else they have never been found), leaving only the acid tektite glass. Furthermore, this one postulated cometary collision would have to be responsible for shaping the different types of tektites in different ways to produce different shape types at widely separated strewn-fields, and would, in some unexplained manner, have to return them to Earth at intervals separated by some 3 or 4 million years. Another cometary collision would then be necessary to explain the Middle Miocene moldavites, and so on, with the result that as many cometary collisions would need to be postulated, and all within the limits of the originally suggested 50 million year cycle of cometary collision, as there has been suggested Great Circles to account for tektite distribution. In other words—a meaningless maze.

Finally, the australites are not consonant with the suggestion of fusion of Earth substance by a high-energy explosion, propulsion to great heights (beyond the atmospheric envelope) with the production of primary forms, and then return to Earth through the atmosphere to generate the secondary shapes.

Admittedly high-speed transit through the Earth's atmosphere has produced the secondary shapes from primary forms. It is not agreed, however, that the composition of australites can be explained in terms of the fusion of the kind of materials exposed at the Earth's surface, and at the same time show the type of chemical gradient according to a provincial distribution across 2,000 miles of the island continent. There is no evidence whatsoever that australites received their primary shapes by upward propulsion from the Earth's surface. None of the known shape types reveal the characteristics shown by volcanic bombs, for example, which are propelled in a plastic state, sometimes to considerable heights, although never, as far as known, high enough to leave the Earth's atmospheric envelope. All the evidence so far accrued is convincing that the australites received their secondary shapes by the modification of primary spheres, spheroids, dumbbells of revolution and apioids of revolution that entered the Earth's atmosphere as solid, non-rotating bodies at ultra-supersonic velocities, traversed the atmosphere at lesser speeds nearer the Earth's surface, passing through a supersonic zone, through the transonic zone and finally into the subsonic zone. During this transit, their leading surfaces were sculptured into the shapes and designs now known from studies of the very excellently preserved, perfectly developed specimens from the Port Campbell district of Western Victoria.

All the evidence points to the fact that the majority of these forms maintained stable positions during high-speed flight through the atmosphere, and while supersonic or higher speeds prevailed, they always presented one surface only to the effects of the aerodynamical phenomena responsible for their secondary sculpture. Moreover, each entity in the swarm, whether original sphere, spheroid, dumbbell or apioid, or even hollow form, behaved in unison with the rest, and each received identical treatment from the medium through which it had its trajectory, so that identical secondary features were produced on the forward surface of each shape type, such features only varying in minor degrees according to the shape types on which they were produced. No secondary shapes have been found that would indicate modification of such geometrically possible forms of revolution as the annular torus and the paraboloid; but this does not mean that they were not present. Some of the so-called 'aberrant' types of australite shapes, which have been subjected to the secondary modification by aerodynamical phenomena in the same way as the better known shape types, were undoubtedly pre-formed shapes before entry into the Earth's atmosphere from outer space. They may have been originally of the paraboloid or annular torus shape types that suffered accidental collapse or other modification in their extra-terrestrial birthplace.

In the face of all these problems and difficulties that beset research work on tektites, I cannot but conclude that cometary collisions spaced at 50-million year intervals are entirely incapable of satisfactorily explaining tektite origin, or of solving the present distribution of widely spaced strewn-fields containing different shape types of tektites that fell to Earth at widely separated intervals. The position still stands as it did approximately seventy years ago, when it was stated about tektites (then referred to as "obsidianites")—"where they came from no one knows". Research since then has shown that for the australites at least, an extra-terrestrial origin of tektite glass is by far the most likely, but it is still unknown whence in extra-terrestrial space the tektites were derived.

LIPOAMINO-ACIDS: THE QUESTION OF ARTEFACT

By Dr. J. J. WREN*

Division of Biology, California Institute of Technology, Pasadena,
and University Chemical Laboratory, Cambridge

THE name 'lipoamino-acid' is proposed for a lipid molecule as normally defined[1] from which one or more amino-acid molecules can be cleaved. For lipoamino-acids in which peptide bonding is known to occur the name 'lipopeptide'[2-7] is appropriate.

There are ever more numerous reports of the existence of lipoamino-acids in lipid samples prepared from many biological materials. Samples demonstrably uncontaminated with free amino-acids or peptides afford various amino-acids on acid hydrolysis. The amino-acids appear to be in covalent linkage, since lipoamino-acids have survived at a wide range of pH values (without heat) and during treatment with salts under various conditions, solvent fractionation (including countercurrent distribution), electrodialysis, electrophoresis, paper chromatography, and column chromatography on alumina, cellulose, 'Hyflo Supercel', and silicic acid. They have even survived treatment with proteolytic enzymes, Van Slyke deamination[8], and dialysis with *N* hydrochloric acid for three days[9].

One lipoamino-acid, phosphatidylserine, has been isolated pure, and its chemical structure is established. Others have only been revealed as minor constituents of mixtures, which in a few cases contained no phosphorus. Their structures cannot be analogous to that of phosphatidylserine, particularly because in many samples hydroxy amino-acids were absent or were present only in small proportions.

Some samples containing lipoamino-acids were devoid of free amino-groups, as indicated by negative ninhydrin tests. For example, in my hands lipid fractions from blood, egg, flies, liver, and milk, eluted from silicic acid by 5 per cent (v/v) methanol in chloroform, under no conditions gave more than a faint yellow ninhydrin colour on heavily loaded paper chromatograms. The sodium 1,2-naphthoquinone-4-sulphonate test[10] was also negative, yet hydrolysis liberated amino-acids. Total amino-acids (chiefly glutamic) liberated from the fly (*Drosophila melanogaster*) fraction[11] amounted to 0·07 mole per kilogram of lipid. They were liberated at 105–110° by alkali as well as by acid, but not by water, and not at atmospheric temperature and pressure by hydrogen with Adams catalyst.

Peptide bonding could account for absence of free amino-groups, but was ruled out for the above fractions, and for some others, by negative chlorination tests[11] and by absence of 'Amide II' absorption in the infra-red (unpublished experiments).

Detection of amino-acids after hydrolysis of lipid preparations does not *necessarily* indicate the occurrence of peptide or protein moieties, and claims in the literature that it does should be viewed critically.

During examination of lipids from several sources by silicic acid chromatography it was noticed that commercial dried blood and egg, and decaying *Drosophila*, gave fractions with higher and more varied amino-acid content than sources believed free from non-enzymic and/or enzymic deterioration. It therefore seemed possible that lipoamino-acids might be artefacts not existing *in vivo*. Binding of nitrogenous substances is a well-known if ill-understood concomitant of lipid autoxidation[12,13], which might occur during extraction and manipulation.

Experiments with linseed oil supported this hypothesis. Raw linseed oil was freed of phospholipids and other contaminants by passage in chloroform through a silicic acid column. (It still contained minute traces of lipoamino-acids.) This oil (10 ml.) was mixed with water (10 ml.), glycine (0·25 gm.), and hæmoglobin (0·1 gm.) in a large test-tube into which a brisk stream of filtered air was passed for 2 days at 25°. The chloroform-soluble portion of the product was chromatographed on silicic acid. Material eluted by pure chloroform afforded only traces of amino-acids on hydrolysis, but material (ninhydrin-negative) eluted by 10 per cent methanol in chloroform afforded approximately 2 mgm. of glycine. Purification by dialysis, instead of by chromatography, confirmed that silicic acid was not responsible for this result. Unreacted, contaminating glycine was only eluted from the column by pure methanol[11]. Leucine and serine, used in place of glycine, gave similar results. When hæmoglobin was omitted from the reaction mixtures, or when the oil was subjected to normal conditions of lipid extraction, no binding of amino-acids could be detected.

However, being less prone to autoxidation than highly unsaturated phospholipids, linseed oil is perhaps not a good model substance.

The following experiment was therefore made. A solution of glutamic acid uniformly labelled with carbon-14 (156 000 counts/min., weight negligible) in moist *n*-propanol was mixed with powder, prepared from *Drosophila* (15 gm.) and dry ice[11], before propanol extraction. The crude extract contained 105,000 counts, 41,000 being retained in ligroin-soluble material (0·82 gm.) which was then chromatographed on silicic acid (12·5 gm.). Specific activities of eluted fractions (in which > 90 per cent of counts were recovered) were determined using thin samples on aluminium planchettes. Results are shown in Table 1. That radioactivity was bound in lipid was demonstrated by paper electrophoresis[3]. Material eluted by 15 per cent methanol in chloroform was placed on a heavily loaded zone of non-radioactive glutamic and 2-pyrrolidone-5-carboxylic acids before electrophoresis. Afterwards, at least 85 per cent of the counts were found in the lipid zone at the origin. Confirmation was provided by 'three-run' paper chromatography (Fig. 1). When lipid eluted by 15 per cent methanol was thus tested zone *U* contained 22 per cent of the counts, *V* + *W* contained 62 per cent, and *X* + *Y* contained 16 per cent. Percentages for lipids eluted by 25 per cent methanol and by 35 per cent methanol were respectively 21, 67, 12 and 27, 30, 43. Zones *U* to *Y* contained fluorescent zones of autoxidation products, which probably accounted for the considerable losses of radioactivity from lipid zones. Significantly, lipid zones did retain more than 20 per cent of their original counts.

---

* Present address: The Lyons Laboratories, Hammersmith Road, London, W.14.

Results also shown in Table 1 are of an experiment in which a considerable weight (1·0 gm. for 8 gm. *Drosophila*) of arginine hydrochloride (372,000 counts/ min.) was used instead of the negligible weight of glutamic acid.

Clearly, some lipoamino-acids are artefacts formed *in vitro* from endogenous amino-acids ; indeed, apart from phosphatidylserine, all of them might be artefacts. This possibility was tested by a series of experiments in which large amounts of selected amino-acids and other compounds ('additives') were added, singly or in pairs, to render concentrations of endogenous compounds insignificant from the beginning of extraction. Extraction and removal of non-lipid contaminants were carried out at low temperature[11].

In a typical experiment blood (50 ml.), collected from a horse, was within 2 min. poured into methanol (100 ml.), plus powdered dry ice (excess), plus additive (10–40 gm. per gm. total lipid). In a room at – 15° lipids were then extracted (total solvent amounted to 400 ml. chloroform–methanol, 2 : 1, v/v) and washed four times by the Folch (1957) sodium chloride procedure[11]. After evaporation of solvent (< 40°) the whole lipid (0·17–0·20 gm., all ligoin-soluble) was chromatographed on a silicic acid column (7·5 gm.). Materials eluted successively by chloroform (60 ml.), by 5 per cent (60 ml.), 15 per cent (240 ml.), and 25 per cent methanol in chloroform (150 ml.), and by methanol (80 ml.) were hydrolysed, and the hydrolysates were examined by paper chromatography[11]. Cow's milk, within 3 min. of milking, was handled similarly, except that additive in aqueous solution was mixed with it immediately before pouring into methanol. Whole *Drosophila* were powdered with dry ice plus additive, as mentioned above. Additives employed were: 2-amino-octanoic acid ; arginine hydrochloride ; ethyl vinyl ether ; guanidine hydrochloride ; hydroxyproline ; mercuric acetate ; monosodium glutamate ; potassium chloride ; sequestric acid ; serine ; α-tocopherol ; urea ; 2-amino-octanoic acid plus ascorbic acid, ethyl vinyl ether, hydroquinone, sequestric acid, tetrahydrofuran ; decylamine plus acetic acid ; glycine plus acetic acid, sequestric acid ; serine plus ethyl vinyl ether, guanidine hydrochloride.

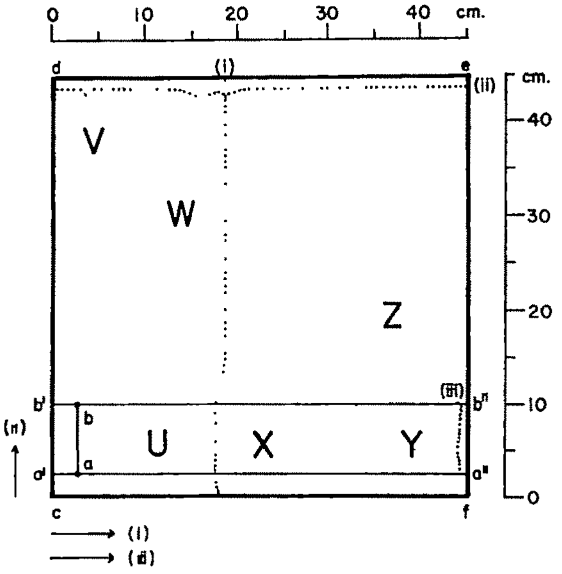

Fig. 1. 'Three-run' paper chromatography, a test for radioactive glutamic acid bound to lipid. Lipid was deposited on a line, *ab*, on a sheet of Whatman No. 3*MM* paper, *cdef*, and chromatographed (i) in benzene/*n*-butanol/methanol/water (1 : 1 : 2 : 1, v/v). After development in the second dimension (ii) with water, the strip *a'a''b'b''* was cut out, and heavy loads of non-radioactive glutamic and 2-pyrrolidone-5-carboxylic acids were applied to *ab* before development (iii) with water. Development was ascending. Numbered, dotted lines represent respective solvent fronts. Lipid formed a zone at *U* and the two acids at *Y*. The paper was treated with ninhydrin, and ultimately cut into several pieces, designated *U–Z*. These were eluted with 25 per cent water in *n*-propanol for radioactivity measurements

Table 1. INCORPORATION OF RADIOACTIVE AMINO-ACIDS INTO *Drosophila* LIPIDS DURING EXTRACTION AND MANIPULATION

Eluant	Counts/mgm./min. of eluted material	
	Glutamic acid	Arginine
$CHCl_3$	0	0
5 per cent MeOH	9 46	1
15 ,, MeOH	7	1 7
25 ,, MeOH	7	7
35 ,, MeOH	116	7
50 ,, MeOH	83	9
MeOH	1,510*	42*

* High values due to elution of the free amino-acids[11].

In control experiments hydrolysates of all but pure chloroform eluates showed fairly constant patterns of amino-acids (for typical patterns see refs. 11 and 14). In many of the additive experiments the patterns were little changed, and in the rest they were changed but not absent. Artefacts formed by several amino-acids, and by decylamine, were detected in amounts comparable with amounts of the usual lipoamino-acids present. For example, in experiments with 2-amino-octanoic acid, this acid appeared in hydrolysates of all except pure chloroform eluates ; it became bound in *Drosophila* lipids if added at any stage before chromatography.

Antioxidant additives failed to prevent the appearance of lipoamino-acids or the formation of artefacts. 2-Amino-octanoic acid formed large amounts of artefact in presence of ethyl vinyl ether, suggesting that vinyl ether groups of the naturally occurring plasmalogens may be involved in artefact formation. Lipoamino-acids do not themselves appear to be plasmalogens, since treatment of whole horse blood lipid with 90 per cent acetic acid at 65° before chromatography did not significantly alter the amino-acid pattern in hydrolysates.

Neglecting the unlikely possibility that in the experiments described above additives failed to equilibrate with endogenous amino-acids, it is concluded that, while some lipoamino-acids are artefacts, others do exist *in vivo*.

Grateful acknowledgement is made to Prof. H. K. Mitchell and Sir Alexander Todd for encouragement, to the Directors of J. Lyons and Co., Ltd., for facilities, and to the Rockefeller and National Science Foundations for financial support.

IS THERE A LEAKAGE OF ACETYLCHOLINE FROM POSTGANGLIONIC PARASYMPATHETIC NERVE ENDINGS?

By Prof. N. EMMELIN

Institute of Physiology, University of Lund, Sweden

WHEN the chorda tympani is cut, a supersensitivity to chemical agents develops in the submaxillary gland, as first shown by Maevsky[1] and Fleming and MacIntosh[2]. A supersensitivity of similar type can be created by treating an animal for some weeks with ganglionic blocking compounds[3] or atropine[4]; since the sensitization is unspecific, secretory agents such as adrenaline can be used to show the effect of atropinization. These observations suggest that the gland cells acquire an increased sensitivity toward chemical stimuli when deprived of secretory impulses[5], and this hypothesis is supported by the finding that some supersensitivity can be produced by cutting afferent fibres of the reflex arc, the lingual or glossopharyngeal nerves[6]. As further evidence in this direction the fact may be quoted that the supersensitivity obtained after section of the chorda can be abolished by daily subcutaneous injections of secretory drugs such as pilocarpine or carbachol; even the responsiveness of the normally innervated gland can be lowered by this procedure[7].

A closer study of the effect of treatment with parasympatholytic agents reveals, however, that the transmitter, released by the nerve impulse, cannot be the only factor which determines the degree of sensitivity of the gland cells.

When atropine treatment is used to create supersensitivity, the doses of the drug have to be increased progressively since tolerance develops; if the initial small dose is given for a long period the sensitivity will first rise, and then decline again in spite of continued treatment (Emmelin, N., and MacIntosh, F. C., unpublished work, 1955). It is therefore difficult to compare the maximal level obtainable by atropinization with that brought about by section of the chorda. By using another parasympatholytic agent, piperidino-ethyl-diphenyl-acetamide (Hoechst 9980), it is possible to produce a marked supersensitivity without increasing the dose of the drug[8]. The supersensitivity obtained in such experiments is found to be much higher than that following section of the chorda[9]. This drug is very specific as a parasympatholytic agent; in the doses used it has, for example, no ganglionic blocking action and does not change the sensitivity to adrenaline in the acute experiment. It therefore seems reasonable to assume that it exerts its sensitizing action by virtue of its parasympatholytic properties. The supersensitivity caused by this drug should then in part be due to the fact that this agent, just as section of the chorda, deprives the gland of the action of acetylcholine liberated by secretory impulses from the central nervous system; but the sensitization above the chorda-level suggests that the drug in addition abolishes some action of a cholinergic mechanism which is left intact when the chorda is cut. In order to test the hypothesis that the supersensitivity caused by Hoechst 9980 is entirely due to loss of action of acetylcholine on the gland cells, some other parasympatholytic agents have been tried: methylscopolamine, lachesine and isopropamide (diphenylcarbamoyl - propyl - di*iso*propyl - methylammonium iodide). They all increase the sensitivity of the gland, all to the same level and to the level characteristic of treatment with Hoechst 9980 (unpublished work).

Section of the chorda tympani is a preganglionic denervation. It leaves the parasympathetic, cholinergic, postganglionic neurone intact. The obvious experiment would be to cut these fibres and investigate whether a supersensitivity ensues which is of the same size as that produced by treatment with parasympatholytic agents. Unfortunately, some of the synapses of the parasympathetic fibres are situated within the gland and not anatomically accessible. Many, however, are found close to the gland but still outside it, and by dissecting the nerve towards the hilum it is possible to produce a partial postganglionic parasympathetic denervation. A supersensitivity is found to develop which is not as high as that produced by treatment with parasympatholytic drugs but more pronounced than that following section of the chorda (unpublished work). Care has to be taken not to damage the postganglionic sympathetic fibres; this in itself would cause a supersensitivity which can be superimposed upon that due to section of the chorda[10]. In the parotid gland of the cat, it is feasible to cut all the postganglionic parasympathetic fibres by section of the auriculotemporal nerves. This operation produces a supersensitivity towards acetylcholine which is larger than that caused by preganglionic denervation[11]. It is, however, not possible to make comparisons between this sensitization and that produced by treatment with parasympatholytic agents because of lack of a suitable test drug; acetylcholine cannot be used since its secretory effect is abolished by such drugs. Adrenaline has to be given in large doses to produce a secretion from the parotid gland, and interfering vascular effects render quantitative comparisons impossible.

The question arises whether there is any indication of an activity in the postganglionic, parasympathetic neurone, apart from that due to impulses from the superior salivary nucleus, which results in a release of acetylcholine. There are two observations which could be quoted in support of the view that small doses of acetylcholine are continuously liberated from the endings of the postganglionic neurone, even when the chorda has been cut.

First, when the submaxillary gland is perfused with an eserinized solution, very small amounts of acetylcholine can be detected in samples of perfusate collected when the chorda has been cut acutely but is not stimulated[12]; this is the case even when the perfusion fluid contains curarine[13].

Secondly, eserine is known to cause a flow of saliva. This effect can be obtained when a small dose of eserine is injected intra-arterially near the gland[14] or through the duct towards the gland[15]. A very small dose, given through the duct, has no effect of its own but increases the secretory effect of injected acetylcholine. If the dose of eserine is raised, a flow of saliva is evoked even when no acetylcholine is administered. It is reasonable to connect this secretory action of eserine with an anticholinesterase effect. This is further supported by the fact that other cholinesterase inhibitors, like *TEPP* and paraoxon, cause a similar secretion. The secretory effect of these drugs is obtained after section of the chorda, and it is then as big as when the chorda is intact. If the secretion is due to acetylcholine, preserved by the esterase inhibitors, this acetylcholine has therefore not been released by impulses from the central nervous system. The secretory effect of eserine remains when the chorda fibres have been cut in advance and allowed to degenerate; after about a week or more it is even larger than for the normally innervated gland because of the sensitization of the gland cells.

Corresponding results are obtained in the parotid gland; but in this preparation it is possible to analyse further the secretory action of anticholinesterases[16]. When the postganglionic parasympathetic fibres have been cut and left to degenerate, eserine injected through the duct has only a very small secretory effect, in spite of the fact that the gland is even more sensitive to acetylcholine than after preganglionic section. Therefore, it seems legitimate to conclude that the main secretory action of eserine is connected with the appearance of acetylcholine originating from the endings of the postganglionic neurone. Such a release cannot be the result of impulses from the cell-body of this neurone, for the secretion is obtained when the postganglionic fibres have been severed acutely; nor is it likely, in such experiments, to be derived from impulses set up from the injured nerve stump, for the secretion is of the same size as that obtained from the contralateral normally innervated gland. A plausible explanation seems to be that there is a leakage of acetylcholine from the postganglionic parasympathetic endings similar to that which takes place at the somatomotor nerve terminals. It was, in fact, suggested already in 1945 by Feldberg[17] that there might be a more or less continuous release of small amounts of acetylcholine from the endings of cholinergic nerves in general. The amounts of acetylcholine released in this way should then be too small to cause any secretion; this would be the case even if the gland cells were sensitized by previous preganglionic denervation. On the other hand, if this acetylcholine should have anything to do with supersensitivity, it must in addition be assumed to exert some kind of action on the gland cells, the removal of which by postganglionic degenerative section or treatment with parasympatholytic agents manifests itself in supersensitivity. A higher level of supersensitivity after post- than after pre-ganglionic denervation is implied in Cannon's 'law of denervation'; leakage of transmitter at the postganglionic endings could provide an explanation for this phenomenon.

In the presence of an anticholinesterase the leaking acetylcholine must be assumed to accumulate to a concentration high enough to cause a flow of saliva. Such a concentration may be reached, under special conditions, even when no esterase inhibitor has been administered. One to three days after section of the postganglionic parasympathetic fibres of the parotid gland, a curious secretory activity can be found[18,19]. The flow is intermittent, occurring in bursts, and has been termed 'paroxysmal secretion'. Since it is abolished by atropine, it seems to be due to acetylcholine. It is, likewise, abolished by cocaine, injected through the salivary duct in a dose which does not change the responsiveness of the gland to injected acetylcholine; it is therefore likely that the acetylcholine responsible for the secretion is of nervous origin. It is reasonable to conclude that the acetylcholine is liberated from the endings of the degenerating nerve fibres. Since the flow persists when a local anæsthetic has been applied to the cut end of the nerve, the secretion cannot be initiated from that site. Acetylcholine seems to be released from the degenerating terminals in bursts in which the threshold concentration for secretion is temporarily surpassed.

RADIOPHYSICS

Global Hydromagnetic Wave Ducts in the Exosphere

In 1957, one of us (H.A.B.) considered the initiation of an earth-magnetic field experiment to detect hydromagnetic waves in the upper ionosphere and exosphere. He suggested the use of very large wire loops (of about 100 km.^{2} area) as pick-up systems for earth-magnetic field perturbations. A large loop has the advantage of a very high signal-to-noise ratio, since it effectively averages out local magnetic interference.

Acting on this suggestion, Berthold and Harris of this Laboratory installed two wire-loop stations (in Arizona and New Jersey), which were operated simultaneously during the summer of 1958. In addition to the advantages due to the high sensitivity of the loops, very accurate synchronization of the two stations was possible. This accuracy made it possible for Berthold and Harris to measure, for the first time, exact time differences in the arrival of sudden commencements at different parts of the world[1].

During the *Argus* experiments of 1958, Berthold and Harris recorded, at both stations, magnetic signals that originated from the high-altitude detonations. Both stations recorded two signals: a fast one, which arrived with a travel time of about four seconds; and a slower one, which arrived about four to five times later than the fast signal[2]. Similar signals were also observed by an earth-current station operated by the U.S. Army Signal Research and Development Laboratory in Maine under the supervision of G. Carp. In addition, the same two signals were recorded during the *Argus* experiments by two stations (Uppsala, Sweden, and Reykjavik, Iceland) operated under the supervision of H. Benioff of the California Institute of Technology, and by a geomagnetic station operated by the U.S. Air Force at the Azores[3]. Table 1, column 2, gives the observed times of arrival of the slow signal at these six stations, and Table 2, column 2, gives the same results for the faster signal.

Table 1. Slow Mode (Transverse Hydromagnetic Mode)

	T (Experimental) sec.	$K \cdot \int f(\varphi)$	P	T (Theoretical) sec.
Arizona ..	26·0	$16{\cdot}55 \times 10^{-26}$	$1{\cdot}57 \times 10^{26}$	24·8

New Jersey ..	4·7	$6{\cdot}92 \times 10^{-26}$	$6{\cdot}80 \times 10^{25}$	4·5
Azores .	4·2	$5{\cdot}95 \times 10^{-26}$	$7{\cdot}00 \times 10^{25}$	3·9

$K = \sqrt{4\pi}/H_0a^3 = 4{\cdot}58 \times 10^{-26}$ [gauss^{-1} . cm.$^{-3}$]
$\overline{P} = 6{\cdot}52 \times 10^{25}$
$P = R^4\sqrt{\rho}$ [cm.^{4} × (gm./cm.^{3})$^{1/2}$]

Arguing that the observed signals were caused by the propagation of hydromagnetic waves due to the sudden displacement of earth-magnetic force lines by the highly diamagnetic fireball, we arrived at the following conclusions: (1) the hydromagnetic waves at high altitudes are essentially confined in ducts, which in first approximation are concentric shells about the earth; (2) within these ducts, the hydromagnetic waves travel essentially along great circle paths; (3) the propagation modes in these ducts are the well-known transverse and longitudinal hydromagnetic-wave modes.

If ds is a line element of a great circle path in the assumed ducts, the travel time between two points is given by:

$$T = \int ds/v$$

If we tentatively identify the slow signal with a generalized Alfvén wave, then $v = v_a\cos\theta$, where $v_a = H/\sqrt{(4\pi\rho)}$, and θ is the angle between the field lines and the direction of propagation. The fast signal should then be identified with the longitudinal hydromagnetic wave, for which $v = v_a$, since in the upper atmosphere v_a is about one thousand times as great as the speed of sound.

Thus, we obtain the following expression for the generalized Alfvén mode of propagation through the duct:

$$T = R^4\sqrt{\rho}\cdot\frac{\sqrt{4\pi}}{H_0a^3}\cdot\frac{1}{2\sin\varphi_0}\left[\ln\frac{\sin\varphi_0+\sin\varphi_2}{\sin\varphi_0-\sin\varphi_2}-\ln\frac{\sin\varphi_0+\sin\varphi_1}{\sin\varphi_0-\sin\varphi_1}\right]$$

where R is the distance of the duct from the Earth (centre to centre); ρ is the ion mass density in the duct; $H_0 = 0{\cdot}3$ gauss (surface magnetic field-strength of the Earth at the equator); $a = 6{,}371$ km. (radius of the Earth); φ_1 and φ_2 are the magnetic latitudes of the site of detonation and receiver stations, respectively; φ_0 is defined as the maximum magnetic latitude of the great circle path, that is, the most northerly point of such a great circle. This value can be readily obtained by elementary trigonometrical computation from the values of φ_1, λ_1, φ_2, and λ_2.

In similar fashion, the following expression is obtained for the longitudinal propagation mode:

$$T = R^4\sqrt{\rho}\cdot\frac{\sqrt{4\pi}}{H_0a^3}\int_{\varphi_1}^{\varphi_2}\frac{\cos\varphi\,d\varphi}{\sqrt{[(\cos^2\varphi-\cos^2\varphi_0)(1+3\sin^2\varphi)]}}$$

where the integral is an elliptical type. The values of this integral for the six stations are given in Table 2, column 3. In both expressions for T, we determined the value of the parameter $R^4\sqrt{\rho}$ that best fitted the experimental data. Table 1, column 5, gives the computed times of travel for the slow mode, and Table 2, column 5, gives the computed times for the fast mode.

The remarkable agreement between theoretical and experimental values, as evidenced by a comparison between columns 2 and 5 of Table 1, and between columns 2 and 5 of Table 2, seems to be a strong empirical indication of the existence of hydromagnetic wave ducts. The existence of such ducts would also explain better the observed intensity and sharpness of the signals received.

By the use of careful compilation of recent observations of ion density as a function of height in the upper atmosphere[4], and current estimates of the composition of the upper atmosphere, we computed the empirical function $R^4\sqrt{\rho}$ versus height, and found that our values for $R^4\sqrt{\rho}$ for the slow and fast modes corresponded to heights of 1,700 km. and 2,500 km. respectively, for the two ducts.

The refraction mechanism needed to bend most of the high-altitude hydromagnetic energy, produced by the detonation, into a very high-altitude duct has not yet been studied in great detail. Also, the correct mathematical relation between wave normal and propagation direction for our case of concentric ducts in an anisotropic medium has not yet been worked out. However, from the well-known formula for the radius of curvature of a beam being propagated in an inhomogenous medium, $r = v / dv/ds$ (where ds is a line element vertical to the direction of propagation), it follows (for longitudinal hydromagnetic waves) that the beam will be bent into a circular path around the Earth at a height where the ion density changes in proportion to R^{-8}. By using the empirical ion density versus height data, we find that this phenomenon occurs at a height about midway between 2,000 and 3,000 km., which independently supports the duct hypothesis.

A more detailed paper is being prepared for publication.

GEOPHYSICS

Tektites and the Earth

The glassy tektites found strewn over the surface of the Earth have long been a scientific enigma. Many hypotheses have been produced to account for their origin and many writers seem to favour an origin beyond the atmosphere, in inter-planetary space. At this juncture it is well to consider several factors that argue against an extra-terrestrial origin.

The bulk constituents of tektites are the same as the constituents of certain sedimentary rocks[1], particularly sandy clays and shales; the twisted silica particles are almost certainly fused grains of sand; tektites are always found associated with sediments. These are arguments in support of the thesis that tektites result from a fusion of the sedimentary rocks of the Earth.

There are notable discrepancies in the percentage of minor constituents of tektites and sediments, but this may be attributed to leaching and weathering processes acting on the sediment before the tektite was formed. The minor constituents that are not subject to differential weathering all support a terrestrial origin. For example, the ratio of nickel to cobalt in tektites is 2·5, in close agreement with sediments[1], while meteorite material invariably shows a ratio between 6 and 60. The deuterium/hydrogen ratio[1] is 0·015 mole per cent, which agrees with the ratio found in the natural waters of the Earth and is considerably higher than the value accepted for non-terrestrial objects. The ratio between strontium-87 in tektites to the total is 0·0702. This value does not correspond to the values for stony meteorites, but agrees closely with the strontium-87 content of sea water and marine sediments[1]. A measurement of the ratio of lead isotopes again shows agreement with terrestrial rocks, and the uranium-thorium-lead balance[1] is more characteristic of Cainozoic sediments than any other material that the astronomer or geologist would expect to find in the entire solar system.

One of the most significant ratios for meteorites is that of iron to nickel, which is usually close to 20 and seldom, if ever, greater than 100. Unfortunately the ratio of iron to nickel on the Earth varies over wide limits for the various types of rock, and is probably affected by differential leaching and weathering in sedimentary deposits. Despite these uncertainties it is of interest to consider the iron-nickel ratio. Tektites show a ratio between 500 and 3,000[1,2], which is considerably higher than that of meteorites and corresponds to the average sediment. Collisions in space are responsible for the dispersal of nickel-iron fragments in stony meteorites and even the surface of the Moon must be contaminated with the 20 : 1 iron-nickel ratio. Thus one would have expected a higher percentage of nickel if tektites were connected in any way with an extra-terrestrial object, whether it be the Moon, an asteroid or meteorite.

Radioactive dating shows that the age of tektites agrees fairly closely with the age of the sedimentary rocks in the tektite area[1]. That is to say, the tektites were probably molten fragments at some instant during the deposition of the sediments. Cosmic-ray bombardment produces helium, neon, argon and other spallation isotopes in the meteorites, which give a measure of the duration of exposure of the specimen in space. So far no measurement has been able to show that the exposure time of tektites is different from zero, and we must conclude that after the melting process tektites were screened from cosmic rays, presumably by the atmosphere of the earth.

These facts offer convincing evidence that tektites were formed on the Earth's surface from sandy sediments by the momentary application of intense and localized heat. I consider that it is more prudent to assume as a working hypothesis that tektites are earthy objects and consider extra-terrestrial origins only when the hypothesis fails.

The suggestion that tektites were produced by the collision of meteorites or comets with the Earth is consistent with a terrestrial origin. The energy of impact would be sufficient to melt the country rock within and around the crater. Impact theories do not adequately account for the widespread nature of tektite fields such as those in Australia and the East

Indies. Furthermore, the original craters have never been found, although we recognize other craters several million years old, nor do tektites contain iron spherules as are found in the glass near recognized meteor craters.

Fusion by lightning has been discounted by many authors[1] because lightning usually produces a long tubular fulgurite whereas tektites are solid and sometimes show pronounced stream-lining or 'flight form'. Fulgurites formed in sand are certainly tubular, but the action of lightning on other sediments, such as a sandy clay, is not known. Recently clay fulgurites, formed in Kingston, Ontario, were brought to my attention by Wallace H. Robb. The objects were partially fused ellipsoids ranging in size from an inch to several inches. We hope to make further studies on these objects. It is perhaps possible for the buttons with flanges, dumbbells and other shapes to be formed by fusion within the ground. It is not correct to assume that these shapes can only be produced by the melting of a tektite during supersonic passage through the air. The usual flight form of meteorites is an irregular cone, the material being blown away as fast as it melts. Meteorites never show flanged buttons, dumbbells, etc.

At Boston University we have commenced a study of tektites, with the support of a N.A.S.A. research grant, and we are considering the hypothesis that tektites are produced by lightning acting on sandy sediments. Lightning offers a ready explanation for the chemical and isotope composition of tektites, their poor annealing and fused silica particles, their age and their widespread yet infrequent occurrence. Artificial tektites have already been produced[2] by the action of a high-energy electron beam on the sandy clay found, on a recent field trip[4], to be associated with the tektites in Texas. Further experiments will continue in an attempt to reproduce the 'flight forms' by fusion, abrasion and etching.

PHYSICS

Time of Residence of Radioactive Debris in the Stratosphere

THE world-wide distribution of strontium-90 from nuclear weapons tests has been extensively studied, especially by the University of Chicago Sunshine Project and others. It has been established that the cumulative deposition has a strong peak in the middle latitudes of the northern hemisphere, and the rate of deposition has repeatedly shown a maximum in the spring.

Libby[1] assumed originally that the debris injected into the stratosphere has a mean time of residence of 10 ± 5 yr. and will be distributed rather uniformly over the globe. He ascribes the peak in the middle latitudes and the increase in deposition in spring to the tropospheric part of the debris.

Based on extensive measurements, Stewart *et al.*[2] have maintained that at places remote from testing areas nearly all strontium fallout is of stratospheric origin. They propose a selective downward mixing of stratospheric debris at middle latitudes, which could explain both the peak and the increase in the spring. Martell[3], however, submits an alternative view; namely, that these phenomena are due largely to recent tests of intermediate- and high-yield weapons which have injected debris into lower and intermediate levels of the stratosphere, debris which has a relatively short time of residence in the stratosphere.

Libby and others[4] now also evaluate the time of residence for stratospheric debris at middle latitudes as considerably shorter, perhaps 2–4 yr.

We have for some time made determinations of the ratio, *r*, of the amounts of strontium-89 and strontium-90 on monthly samples of precipitation from a number of stations in Denmark, including the Faeroes and Greenland. The location of the stations, given to the nearest degree, are as follows:

		Longitude	Latitude
B	Oestermarie, Bornholm	15 E.	55 N.
C	Copenhagen, Zeeland	13 E.	56 N.
T	Thorshavn, The Faeroes	7 W.	62 N.
G	Groennedal, Greenland	48 W.	61 N.
S	Soendre Stroemfjord, Greenland	50 W.	67 N.

Our results are given in Fig. 1. The accuracy of the measurements varies with the strength of the samples as shown.

It can be seen that the ratio *r* in August and September 1958 is around 15. As part of the fallout may be tropospheric, $r = 15$ is an upper value for debris from the stratosphere at that time. The ratio increases in October for some (the northernmost) stations to a little less than 40. From February 1959 it again decreases for all stations. The two dotted lines are drawn with a slope corresponding to the decay of strontium-89.

We believe that the two results for Copenhagen in October and November indicate that very little dust from explosions in October reach Copenhagen before December.

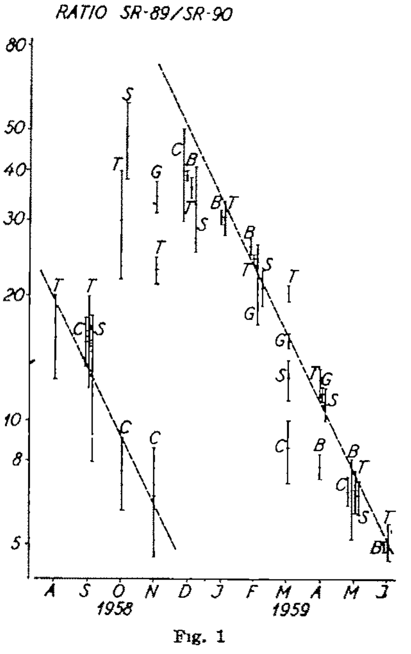

Fig. 1

The results for the period January–June follow the slope of the lines remarkably well. Combined with the cessation of weapon tests around November 1, this seems to show that for a period of five–six months starting two–three months after the last injections in the stratosphere, and for 5 stations distributed nearly along a line 2000 miles long, the composition of the fallout corrected for the decay is very uniform.

Since the time of residence in the troposphere is much shorter and stratospheric debris from older tests would give a lower value of *r*, it is concluded that a considerable part of the fallout in the spring of 1959 over a large area was stratospheric, but originated from the tests in northern latitudes in the autumn of 1958.

From the increase in *r* as given by the vertical distance between the two lines in Fig. 1, it is inferred that 40–50 per cent of the strontium-90 fallout in the period February–June comes from these tests.

These measurements are part of work carried out for the Danish Defence Research Board, and I thank the Board for permission to publish these results.

Measurement of Ion Beam Currents using a Hall Effect Magnetometer

Ion and electron beam currents are normally measured in terms of either a collected current or the beam power dissipated in a calorimeter. Direct-current collection is complicated by secondary emission at the collector surface, and calorimeters are difficult to use when the beam power is low. For both methods the beam must be interrupted in order to measure the current. The technique described here avoids these disadvantages by measuring the magnetic field associated with the particle beam.

The magnetic field-strength in the vicinity of a beam of charged particles is given by $H = i/5r$, where i is the net current in amperes and r the radial distance in cm. from the beam axis. If $i = 1$ m.amp. and $r = 1$ cm. then $H = 2 \times 10^{-4}$ oersted. Fields of this intensity have been detected using the Hall effect in indium antimonide[1]. If the magnetic field generated by the beam is concentrated on the indium antimonide crystal then currents smaller than one milliampere may be detected.

A 'Mumetal' rod 1·3 cm. in diameter was bent into a 6·0-cm. diameter ring and annealed. An indium antimonide crystal 0·025 cm. thick was placed in a 0·040-cm. air gap built into the ring. This indium antimonide magnetometer was used in conjunction with a transistor oscillator and amplifier. In order to demonstrate the principle the ring assembly was mounted in a vacuum chamber through which passed a 1·0-cm. diameter electron beam of 1 keV. energy. Two current balancing loops, as shown in Fig. 1, were used to cancel the magnetic field due to the beam. The magnetometer was then used as a null indicating device and at the null point the beam current equalled the current through the balance loops.

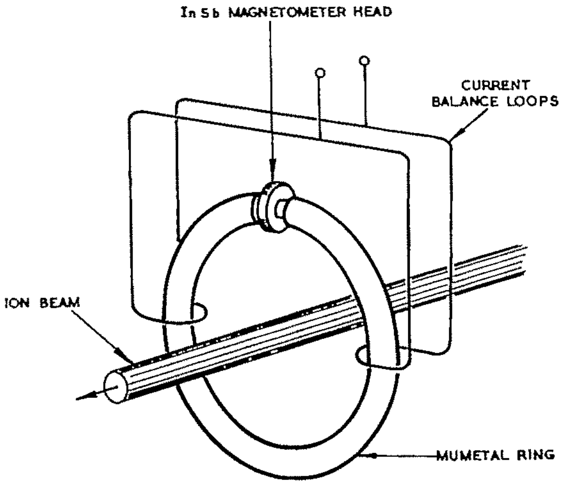

Fig. 1. Schematic diagram of magnetometer ring assembly

Two methods of applying the magnetometer were investigated. In the first method a steady electron beam was directed through the ring with the crystal excited by a 1 kc./s. alternating current. A balance was obtained by adjusting the current through the balance loops until the value of the 1 kc./s. Hall voltage equalled that for zero beam current. The smallest beam current detectable above the noise-level was about 10 μamp. Although a balance was easily obtained for larger currents the accuracy of the device was mainly limited by the zero drift caused by small changes in temperature of the crystal unit. Displacement of the beam from the centre of the ring did not appear to alter the balance condition.

In the second method the crystal was excited by a steady direct current while the beam was modulated at 1 kc./s. Only the alternating component of the Hall voltage was fed into the amplifier. In this case zero drift was virtually eliminated and the smallest detectable current was slightly less than 10 μamp.

The technique offers a new experimental approach to certain problems involving ion beam current measurement. Ionic processes may be studied without the complications associated with conventional detectors.

We are grateful to Miss P. Dunmow and Mr. N. A. C. Thompson for their help in the experiments. Permission to publish has been granted by the Admiralty.

Cavity Formation in Simple Pipes due to Rupture of the Water Column

When the water-hammer surges that accompany rapid velocity changes in pipes are of such a kind as to produce a fall to vapour pressure, cavities are formed. Theory and analysis at present available rest largely on empirical evidence of changes in pressure alone. In the case of rupture, a recent publication appears to support methods of analysis already in use[1], and suggests cavity formation would take place at the control (gate) end of a straight horizontal pipe.

Studies of the changes in pressure at the centre of a 60-ft. horizontal length of 1-in. copper tube as well as near the control end suggest a new but logical development of the normal theory. The usual principle of the independence of the direct and reflected waves expressed in the basic wave equations can no longer be tacitly accepted, and any such waves which may meet along a pipe must be algebraically summed to ascertain whether the resultant pressure tends to yield a value less than or equal to vapour pressure. It is believed that such a tendency will be invariably found to exist during all rupture periods that occur with the exception of the first. Because pressures less than vapour pressure cannot be tolerated, additional cavity formation is necessary to ensure compatibility of pressure and velocity changes.

Fig. 1 illustrates the result of the theoretical analysis proposed for a specific example. Additional cavity formation occurs at point *D*, due to the simultaneous arrival at this point of a normal reflected wave and a new direct wave occasioned by the resurge of the water column at *A* at the end of the first rupture phase.

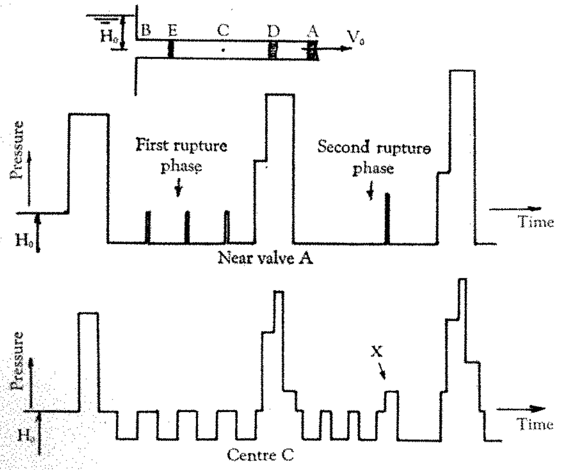

Fig. 1. Graphical solution for rupture

The cavity at *D* in the example shown disappears before the normal cavity at *A*, and evidence of this is seen in the positive pressure rise (marked *X*) at *C* during the second rupture phase. In the case shown further peculiarities of the pressure variations are due to the formation of a complementary cavity at *E*.

Pressure records support the theory, and also observations of a transparent pipe with photographic aid confirm the formation of the cavity as predicted.

It is considered that analytical and experimental investigations of this cavity formation will enable: (a) The phenomenon of rupture of the water column to be explained. (b) The growth and decay of cavities under the action of estimable forces to be described, including the effects of entrained air. (c) The assumed mathematical relationship between pressure and velocity changes to be studied, in view of the fact that the moving cavity serves as an index of water velocities that exist during certain phases.

Work which has been in progress for some time is proceeding along these lines.

METALLURGY

A Model of Metal Fatigue

The important part played by the disturbance of the surface of a fatigue specimen by to-and-fro slip movement in the slip bands has been emphasized by much recent work, especially that of W. A. Wood[1]. If the slip in alternate cycles were exactly reversed in the same atomic planes, then there would be no surface disturbance. On the other hand, extrusions or intrusions will be formed if by some mechanism such as that proposed by Mott[2] the dislocations which have moved in one direction along a certain path return by a different one, so as to go round a closed circuit in the same sense at each cycle. There is another possibility: that the dislocations make their return journeys along paths which are shifted in a random fashion with respect to the previous paths. If the shifts are comparable with the width of the slip band, this is equivalent to assuming that the slip is distributed at random at each half-cycle among the available slip planes, and that the distribution of slip at each half-cycle is independent of the distribution of slip in previous cycles.

This random distribution of slip will roughen the surface, each part of which is engaged in a random walk along the slip vector. This roughening will lead to a re-distribution of the stress, so that in later cycles the slip will tend to be concentrated in the valleys already formed on the surface. The subsequent surface movements will make some of the valleys less deep, but some will become deeper, and on these the slip will be even more concentrated. I have set up a rough model of this process in mathematical form, in order to see whether valleys deep enough to lead to cracks could be formed in a reasonable number of fatigue cycles.

These calculations will be published elsewhere. The main result is that after t cycles the fraction f of the valleys of width w which have depths between z and $z + dz$ is given by:

$$f = F \exp - [\{\sqrt{(z + w)} - \sqrt{w}\}^2 / b\,\varepsilon\,t]$$

where F is a slowly varying function of z, w and t. The slip vector b and the plastic strain ε in the slip band are taken as constant. The distribution consists of a Gaussian peak near $z = 0$ and an exponential tail at large z governed by the factor $\exp - z/b\varepsilon t$.

If we suppose that at some large value of z, say Z, the valleys become deep enough to form cracks, we can regard $Z/b\varepsilon$ as a time constant T controlling the rate at which valleys attain the depth Z, and therefore the life-time of the specimen. The first valleys will attain a depth Z after approximately $T/15$ cycles.

It remains to make a rough estimate of the numerical magnitudes involved. We suppose that a valley with a depth ten times its width can be regarded as an incipient crack. Thus $Z \sim 10w$, giving $T \sim 10w/b\varepsilon$. If we insert as typical values, $w = 10^{-4}$ cm., $b = 5 \times 10^{-7}$ cm. (corresponding to the passage of a group of about 20 dislocations at each slip), and $\varepsilon = 10^{-3}$, we get for T about 2×10^6 cycles. The first incipient cracks will appear at about $1{\cdot}3 \times 10^5$ cycles. The satisfactory agreement with the order of magnitude found in practice for life-times suggests that it would be worth while to investigate a more realistic model of this type.

Oxidation of Titanium–Iron Alloys

Above the transition temperature, the oxidation of titanium proceeds by a layer of titanium oxide (TiO_2) growing outwards by the migration of anion vacancies. Concurrently, a solid solution layer of alpha-titanium containing dissolved oxygen grows inwards. The alpha-layer is fairly uniform in thickness over the surface of the specimen. Micro-hardness measurements show a very marked hardness gradient across it, indicating an oxygen concentration gradient and suggesting that the rate of growth of the alpha-layer is controlled by the diffusion inwards of interstitial oxygen.

It has been found that the addition of small amounts of iron to titanium, while not markedly affecting the overall rate, modifies the structure of the alpha-layer. Alpha-plates form rapidly along some of the beta grain boundaries, plates about 0·5 mm. long forming in about 15 min. at 875°C. Later, the alpha-plates thicken slowly, and a two-phase alpha/beta layer of roughly uniform thickness is formed around the specimen and grows inwards. There is no hardness gradient within the alpha-plates, suggesting that oxygen diffusion is not the controlling step in their formation.

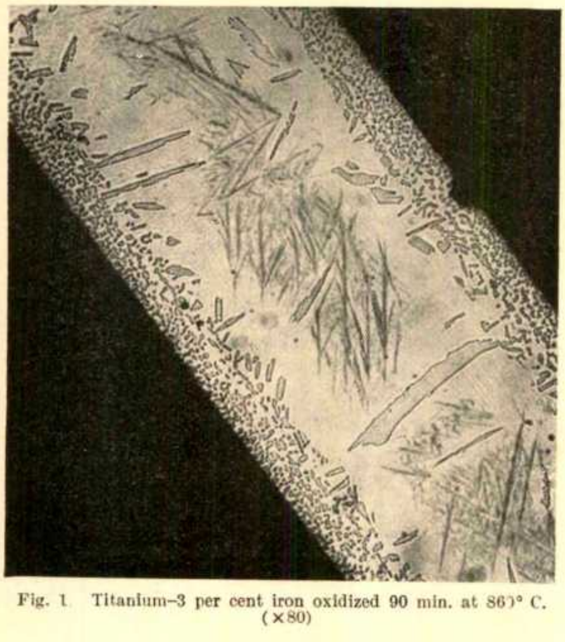

Fig. 1 Titanium–3 per cent iron oxidized 90 min. at 860° C. (×80)

However, when a specimen containing 3 per cent iron is quenched after oxidation, only the beta-phase remote from the alpha-plates is transformed martensitically, as is shown in Fig. 1. Duwez[1] has shown that above 4 per cent iron the martensite start temperature is less than room temperature and beta-phase is retained. From this it is deduced that the iron content in the beta-phase adjacent to the alpha-plates is greater than 4 per cent. Alpha titanium does not dissolve iron to an appreciable extent[2] and it would appear that the iron ejected from the advancing alpha-plates raises the concentration of iron significantly. It is not possible to determine the variations in the iron content of the beta-phase by micro-hardness measurements, because in the neighbourhood of 4 per cent iron the hardness of quenched titanium varies very little with iron content[3]. The oxygen content, as indicated by the hardness of the alpha-phase[4], is about 2 per cent by weight at 850°C. and 2·5–3 at 900°C. which, if local equilibrium is assumed, indicates an iron content of about 6–7 per cent by weight[5].

It is concluded, therefore, that there is an iron gradient in the beta-phase from the original 3 per cent at the centre of the grains remote from the alpha-plates to about 6 per cent by weight at an alpha/beta interface. The rate of thickening of the alpha-plates, and the rate of thickening of the alpha/beta two-phase layer at the specimen surface, are apparently determined by the rate of diffusion of iron away from the interface.

RADIOCHEMISTRY

Preparation of Radiochemically Pure Tritium Nuclear-labelled Morphine

Morphine has been labelled with carbon-14 in the N-methyl position by chemical synthesis[1,2] and randomly by biosynthesis[3,4]. Because of the metabolic lability of the N-methyl group and the need for considerable quantities of a product of high specific activity, studies on the preparation of tritium-nuclear labelled morphine were initiated. The Wilzbach procedure[5] of exposure to tritium gas was utilized for the introduction of the tracer element into the morphine molecule. The preparation of biologically stable tritium-labelled morphine by this technique had been described previously[6], and the radiochemical purity of the product was reported. We have found, however, that the exposure to tritium gas of morphine base or morphine sulphate in finely divided form, and subsequent purification to remove the labile tritium and radio-decomposition products, uniformly gave a seemingly pure crystalline morphine which showed two distinct areas of radioactivity when paper chromatograms were developed using correctly buffered paper and the proper solvent mixtures. One area contained a greater proportion of radioactivity (approximately 65–70 per cent of total) but negligible mass of material (not detectable by spray reagents or by visualization with ultra-violet light, less than 1 per cent). Similarly when normorphine base or its hydrochloride was tritiated in the same manner and purified, the morphine synthesized from it by the method of Andersen and Woods[1] showed the same trace radio contaminant. When paper chromatograms were prepared from the above tritium-labelled 'morphine' using non-buffered paper and several solvent mixtures, that is, *n*-butanol, formic acid, and water (12 : 1 : 7 v/v); 2·3 per cent *p*-toluene sulphonic acid in *n*-butanol and water (100 : 14-v/v), etc., all the radioactivity was located in one area. This area was the alkaloidal spot as localized by spraying with iodoplatinate alkaloidal reagent or by visualization of the shadow with ultra-violet light. The R_F values were identical with parallel non-labelled morphine.

Paper chromatograms obtained with paper buffered at *p*H values varying between 5·6 to 8·0 (Table 1) and the solvent systems of *tert*-amyl alcohol and water or *tert*-amyl alcohol, *n*-butyl ether and water (80 : 7 : 13 v/v)[7], effected a separation of the radioactive impurity from morphine. By the use of co-chromatography with non-radioactive dihydromorphine, the paper chromatograms gave presumptive evidence that the radiochemical impurity in the tritium-labelled 'morphine' was tritium-labelled dihydromorphine. Separation of the two areas of radioactivity was not possible when the paper was buffered at higher *p*H values, namely, 9·25.

Crude tritium-labelled normorphine hydrochloride was converted to free base, crystallized from methanol and the product reprecipitated from an acetic acid solution by dilute ammonia. (The exposure was performed by the New England Nuclear Corp., Boston, Mass.) The normorphine was converted to morphine by the method of Andersen and Woods[1]. The specific activity (128 μc./mgm.) of the resulting morphine did not change on three serial crystallizations. The amount of the trace radiocontaminant remained unchanged or was only partially removed by vacuum sublimation of the 'chemically pure morphine', or fractional crystallization of its diacetyl derivative followed by the conversion of acetylated product back to morphine. Attempts to remove the tritium-labelled dihydromorphine with basic or acid-washed alumina columns, or cellulose columns, were not successful.

Table 1. TYPICAL R_F* VALUES OF COLD AND RADIOACTIVE MORPHINE AND DIHYDROMORPHINE CALCULATED FROM CHROMATOGRAMS OBTAINED WITH WHATMAN No. 1 PAPER

Compound	*p*H of buffer solution applied to paper				
	5·7^a	7·0^b	7·2^b	7·9^b	9·25^c
Morphine	0·56	0·28	0·37	0·66	0·82
Tritium-labelled morphine	0·55	0·29	0·36	0·65	
Dihydromorphine (non-labelled)	0·41	0·15	0·18	0·54	0·82
Tritium-labelled 'dihydromorphine'	0·40	0·17	0·15	0·56	
Mixture of known non-labelled dihydromorphine and eluted area of tritium labelled 'dihydromorphine'	0·40				

The paper strips were dipped in the 0·2 *M* buffer solution, allowed to drip dry in a hood for 1–2 hr., placed in a glass cylinder containing the solvent mixture for 12–14 hr. (overnight) and the chromatogram then developed with the selected solvent mixture. The scanning of dried chromatogram strips was done by eluting 1-cm. strips with absolute methanol, evaporation in counting vials and subsequent counting in a Packard Tricarb liquid scintillation spectrometer.

* The values are not meant to be absolute and may vary somewhat with temperature, nature of buffer used or extent of saturation of paper in chamber. Non-labelled compounds were run as references in all experiments. The temperature was 23·5° ± 0·5° C. The values for radioactive compounds were calculated from the centre of maximum radioactivity.

[a] *Tert*-amyl alcohol, saturated with 1 : 1 (v/v), 0·2 *M* acetate buffer (this buffer was also used to saturate the paper).

[b] *Tert*-amyl alcohol, *n*-butyl ether and water (80 : 7 : 13 v/v) and paper buffered with 0·2 *M* phosphate buffer.

[c] 0·2 *M* borate buffer; solvent mixture as in footnote *b*.

Radiochemically pure morphine was separated by descending chromatography on Whatman 3 *MM* paper (5 mgm./large sheet) buffered with 0·2 *M* phosphate buffer, *p*H 7·0, and developed with a *tert*-amyl alcohol, *n*-butyl ether and water (80 : 7 : 13) system. The morphine band located under ultra-violet light was extracted with absolute methanol in a Soxhlet extractor.

The methanol extract was mixed with cold carrier and evaporated to dryness under nitrogen and reduced pressure. The morphine was separated from this residue and passed over a small neutral activated alumina[8] column to give pure morphine base. The specific activity was about 5–10 μc./mgm. with a one to three isotope dilution with cold carrier. The same procedure using cold dihydromorphine as carrier gave radiochemically pure dihydromorphine.

Morphine exposed to tritium by the Wilzbach procedure shows addition at the 7 : 8 double bond giving the dihydro-radiocontaminant having a negligible amount of total mass but a greater fraction of total radioactivity. Since this material is not biologically identical with morphine, it is essential to remove the former from morphine to be studied biologically. A detailed report will appear elsewhere.

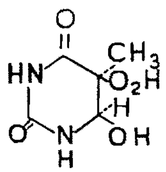
RADIATION CHEMISTRY

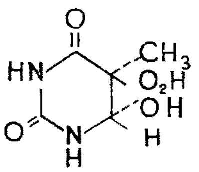
Organic Hydroxy-Hydroperoxides: a Class of Hydroperoxides formed under the Influence of Ionizing Radiations

IN continuation of our previous work on nucleic acids and related compounds[1], it has now been found that many substances, when irradiated with, for example, γ-rays, X-rays, in aqueous solution in the presence of oxygen, are capable of forming hydroxy-hydroperoxy compounds, many of which were previously unknown.

Compounds belonging to this class which may be of interest from a biological point of view are the hydroxy-hydroperoxides, which are formed from different pyrimidine bases, for example, thymine and uracil. Among these, the thymine hydroxy-hydroperoxide is rather stable and can be isolated from the irradiated solutions. In support of an earlier suggestion[2], it has now been found that the peroxides produced by radiation are the (*cis*) and (*trans*)-4-hydroxy-5-hydroperoxide (I) and (II):

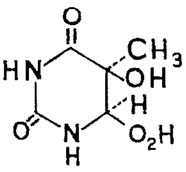


(I)

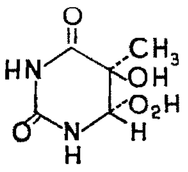


(II)

It is of interest to note that these compounds are not decomposed by catalase. The isomeric 5-hydroxy-4-hydroperoxide should also be possible in a *cis* and *trans* form, so that in addition to (I) and (II) the following compounds may exist:



(III)



(IV)

All these compounds have in fact now been made from thymine by chemical methods by Dr. B. Ekert[3] at the Pasteur Institute. They can be separated, for example, by paper chromatography by means of the solvent system *n*-propanol (80 parts), *N* hydrochloric acid (15 parts) on Whatman No. 1 paper and can also be characterized in this way.

Another convenient way of characterizing these different hydroperoxides was found by measuring the rate constants for the liberation of iodine in the reaction of the hydroperoxide with iodide in aqueous solution. The second-order rate constants for the different hydroxy-hydroperoxides from thymine are given in Table 1:

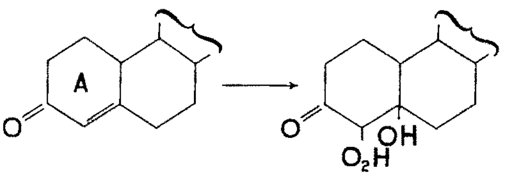
Table 1. RATE CONSTANTS FOR THE REACTION OF DIFFERENT HYDROPEROXIDES WITH IODIDE AT *p*H 4 0 AND 25° C. (Measurements carried out by Mr. J. F. Ward)

Compound	Rate constant (l. mol.$^{-1}$ sec.$^{-1}$)
Hydroperoxide by radiation from thymine	1·59
4-Hydroxy,5-hydroperoxy thymine (I, II)	1·60
4-Hydroperoxy,5-hydroxy thymine (III, IV)	7·58
Hydrogen peroxide	1·18 × 10^{-2}

The rate constant for hydrogen peroxide, measured under the same conditions, has also been included: a comparison of the values shows that the thymine hydroperoxides are very much more reactive than hydrogen peroxide. The rate constant of the compound produced by radiation is practically identical with that of the 4-hydroxy,5-hydroperoxy isomer. The 4-hydroperoxy,5-hydroxy compounds (III, IV) are, under the conditions in question, nearly five times more reactive than the isomer with the hydroperoxy group in the 5-position. On the other hand, we could not detect any appreciable differences between the corresponding *cis* and *trans* isomers. The reason for this may be that either the differences are too small, or in solution a relatively rapid *cis–trans* isomerization takes place.

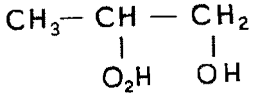
Uracil also forms a corresponding hydroxy-hydroperoxide which is of comparable stability; on the other hand, the hydroperoxide from cytosine appears to be much less stable in solution.

Another new group of hydroxy-hydroperoxides has been obtained from various steroids by means of ionizing radiations[4]. Peroxides derived from steroids have recently again attracted some interest as possible sources of the carcinogenic effects of such substances. The compounds described by Fieser *et al.*[5] and Schenck *et al.*[6] are ordinary hydroperoxides. The study of the action of ionizing radiation on aqueous solutions of, for example, deoxycorticosterone, cortisone and related steroids has shown that these and similar steroids are capable of forming hydroxy-hydroperoxides. Although these compounds have not yet been isolated in a pure form, their chemical and spectroscopic behaviour shows clearly that the OH and HO_2 attach themselves to the double bond of ring *A*, namely:



and/or the corresponding isomer with the OH and HO_2 groups exchanged, which may also be formed to a lesser or greater extent. There are, of course, again two possible stereoisomers for each structure. This type of structure is supported also by the disappearance of the ultra-violet absorption associated with the chromophoric α,β unsaturated ketone grouping in ring *A*. In the case of deoxycorticosterone, which has been studied in some detail, it has been found that two different hydroperoxides are formed in the ratio of approximately 2 : 1. In addition to the hydroperoxide on ring *A*, a second one, which is associated with the side-chain, is also formed, as was shown by a corresponding decrease in the tetrazolium blue reaction.

With regard to some simpler olefinic molecules, it may be of interest to note that propylene forms a hydroxy-hydroperoxide in a comparatively high yield ($G = 2{\cdot}6$ mol./100 eV.) when irradiated in aqueous solutions in the presence of oxygen. The structure of this hydroperoxide was found to be (Clay, P. G., and Whiston, J., unpublished results):



$$\begin{array}{ccccc} CH_3- & CH & - & CH_2 \\ & | & & | \\ & O_2H & & OH \end{array}$$

It can thus be stated that, in general, the action of ionizing radiations on ethylenic systems in the presence of oxygen can give rise to more or less stable hydroxy-hydroperoxides. These compounds may be of considerable biological interest, and bearing in mind the important and unique role of oxygen in connexion with the radiosensitivity of living cells, further study of the biological effects of such compounds is desirable.

We thank Dr. B. Ekert for supplying us with samples of the synthetic thymine hydroperoxides and the Rockefeller Foundation for financial support.

Electron Paramagnetic Resonance Observations on Irradiated Thiols and Disulphides

THE unique role of sulphur in radiation damage is amply borne out by recent electron paramagnetic resonance work[1–3]. In a current investigation on the mechanism of action of the sulphur-containing radioprotective compounds, quantitative electron paramagnetic resonance studies have been carried out on a series of irradiated thiols and disulphides.

The substances were irradiated in the polycrystalline state at room temperature with conventional X-rays (220 keV.). Irradiations were carried out in vacuum as well as in air. In most cases, the radiation doses were less than 5×10^5 r. The spectrometer used operates at a frequency of 9,200 Mc. per sec. The spectra obtained represent the first derivative of the actual absorption curves. Quantitative results were obtained by double integration and comparison with measurements on standard systems. The more significant observations may be summarized as follows:

Dose-effect relationships. The qualitative electron paramagnetic resonance spectra exhibited in some instances a continuous and distinct change with increasing radiation dose, even in the comparatively low dose-range used (Fig. 1). Moreover, for all compounds studied the number of resonance centres detected did not increase linearly with the radiation dose, as exemplified in Fig. 2. This dependence of the yield on the radiation dose may in part explain the large discrepancies found in the literature concerning the number of electron volts needed to produce free radicals[4–6].

Time effects. The number of detectable paramagnetic resonance centres showed an unexpected relationship to the time elapsed after the irradiation. For some compounds (for example, cystine, penicillamine) the number of free radicals N seemed to decay in vacuum according to the general equation: $N = a \ln (t) + b$, where t is the time and the parameters a and b vary with the substances. In the case of other compounds (for example, homocystine, cystamine), the number of resonance centres increased by approximately 10–20 per cent during the first hours after the irradiation. In these instances the peak was reached in 3–4 hr. and the number then decreased, the decay obeying the general formula stated above. The quantitative changes were associated with qualitative changes in the electron paramagnetic resonance spectra in the case of homocystine and cystamine. The spectra of cystine and penicillamine, on the other hand, were constant with time.

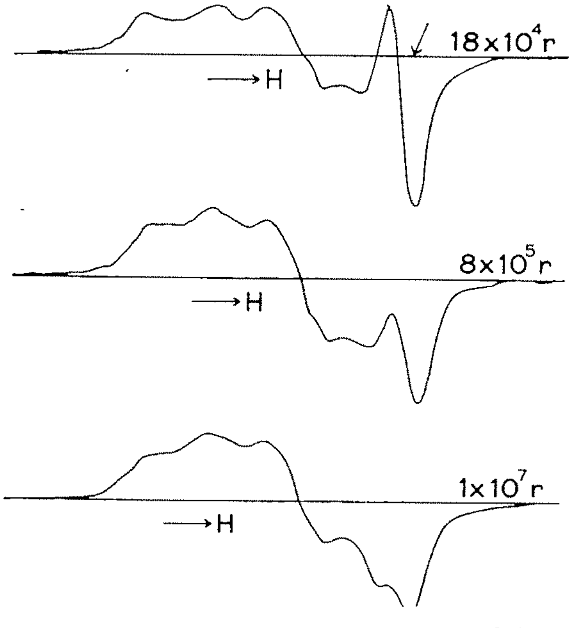

Fig. 1. The effect of the radiation dose on the qualitative electron paramagnetic resonance spectra of cystamine dihydrochloride irradiated in vacuum. The measurements were carried out 30 min. after the conclusion of the exposure. The arrow indicates the position of g-factor of free electron spin. The total width of the spectrum is about 150 gauss

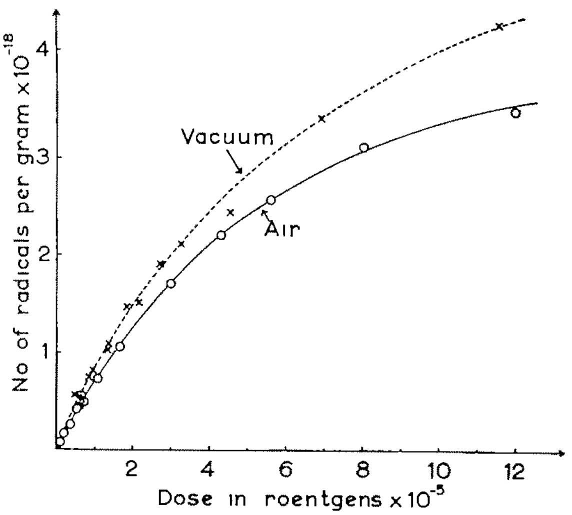

Fig. 2. The relationship between the radiation dose and the number of paramagnetic resonance centres induced in cystamine dihydrochloride. From the curves, 'initial yields' (calculated from the straight line portion of the curves) were found to be 7 and 8 eV. per induced spin in vacuum and in air, respectively

The observed increase in the number of resonance centres in the case of homocystine and cystamine suggests the possibility that several types of free radicals are initially formed, one of which may decay with the formation of two or more other types. The concurrent qualitative spectral changes may be taken to support this view.

Structural effects. In contrast with previous views[1], structural factors were found to exert a pronounced effect on the qualitative electron paramagnetic resonance spectra of thiols and disulphides (Fig. 3). Whereas cysteamine, cysteine, and cystine gave closely similar resonance patterns, marked differences were obtained when the carbon chain was extended (for example, 1-mercapto-7-aminoheptane, homocystine) or branched (for example, penicillamine). Substitutions in the amino group (N,N′-tetramethylcystamine, N-morpholyl-cysteamine, N-piperidylcysteamine) likewise resulted in pronounced changes in the resonance patterns. In general, these chemical alterations introduced a hyperfine structure in the high-field part of the spectra.

The above-mentioned findings bear out the fact that electron paramagnetic resonance measurements are influenced by several parameters which must be clearly defined in qualitative as well as in quantitative electron paramagnetic resonance studies. They also demonstrate that the chemistry of the radiation of thiols and disulphides in the dry state is more com-

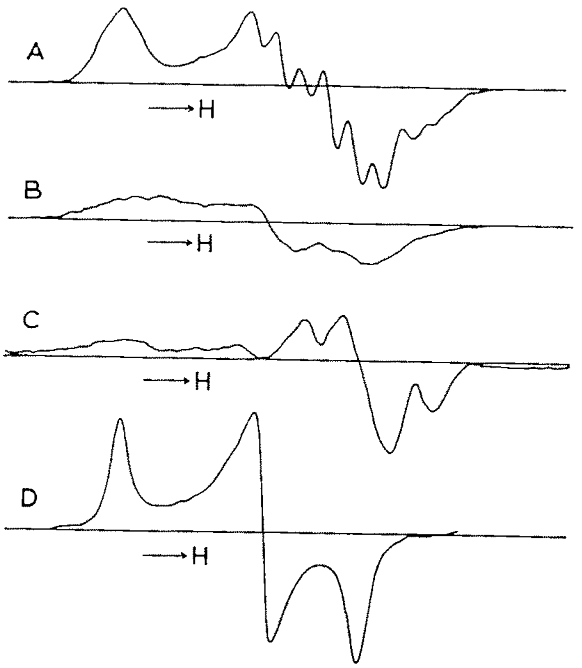

Fig. 3. Examples of variations in the qualitative electron paramagnetic resonance spectra with variations in the chemical structure. Dose, 5×10^4 r. Otherwise, conditions as in Fig. 1. *A*, N,N′-tetramethylcystamine dihydrochloride; *B*, *l*-cysteine hydrochloride; *C*, reduced glutathione; *D*, *d*-penicillamine. In the course of 2–3 days, the spectrum of glutathione changed to resemble closely that of cysteine

plex than previously recognized. The distinct differences observed between the spectra of various thiols and disulphides open up the possibility of studying the chemical properties of irradiated mixed disulphides, a question which is of interest from a radiation protection point of view[7,8]. Such studies are in progress.

The details of this work will be published elsewhere.

CHEMISTRY

Experimental Test of Verwey and Overbeek's Theory

Ghosh and Rakshit[1] have measured the ζ-potentials of a titanic oxide sol in the presence of equicoagulating concentrations of electrolytes. An attempt has been made here to calculate the ζ-potentials of the colloid particles of a titanic oxide sol at flocculating concentrations of electrolytes from an analysis of the nature of the curves of total potential energy of interaction of two spherical colloid particles, and to compare these calculated values with those obtained by Ghosh and Rakshit by electro-osmotic measurements.

The total potential energy V is calculated from the following expression:

$$V = V_R + V_A \qquad (1)$$

where V_R and V_A are the repulsive and attractive potential energies of interaction of two colloid particles respectively.

Derjaguin[2] has shown that for small surface potential ψ_0 and large values of $\varkappa a$ the repulsive energy V_R of interaction between two colloid particles, each of radius a, can be calculated from the following expression:

$$V_R = \frac{Da\psi_0^2}{2} \ln \left[1 + \exp\{-\tau(S-2)\}\right] \qquad (2)$$

where D is the dieletric constant and τ and S are equal to $\varkappa a$ and R/a respectively, where R is the distance between the centres of two colloid particles.

Hamaker's[3] expression for the attractive energy V_A of interection of two spherical particles can be written in the following form:

$$V_A = -\frac{A}{6}\left[\frac{2}{S^2-4} + \frac{2}{S^2} + \ln\frac{S^2-4}{S^2}\right] \qquad (3)$$

where A is the Van der Waals–London constant.

In order to calculate the values of V from equations 1, 2 and 3 it is necessary to know the values of $\varkappa$, a and A. The values of $\varkappa$ have been calculated from the following expression:

$$\varkappa = \sqrt{\frac{4\pi\varepsilon^2 \Sigma n_i z_i^2}{DkT}} \qquad (4)$$

where ε is the electronic charge, D the dielectric constant of the medium, k the Boltzmann constant, n_i the number of ions of the ith type per c.c. of the solution and z_i is its valency. Taking $T = 35°$ C. and $D = 75$, the values of $\varkappa$ at flocculating concentrations of electrolytes are calculated from equation 4 for a titanic oxide sol[1] and given in column 3 of Table 1.

Table 1

Titanic oxide sol

Electrolyte	Concentration of electrolyte ($N \times 10^3$)	$\varkappa \times 10^{-6}$	ζ observed (mV.)	ζ calculated (mV.)
$K_4[Fe(CN)_6]$	2 86	0·8847	10 3	13·94
Na_3-citrate	2 72	0 7716	9 0	12·93
Na_2SO_4	4·5	0 8596	12 8	13 72
NaCl	103 00	3 357	28 2	28·2
$K_4[Fe(CN)_6]$ + NaCl	1 43 51·50	2 456	25·0	23 97
Na_3-citrate + NaCl	1 33 51 5	2 435	24·8	23 85
Na_2SO_4 + NaCl	2 237 51 5	2 45	24·2	23·95
Na_2SO_4 + NaCl	4 114 5 15	1 114	16·1	15·86

Since the colloid particles increase in size rapidly before they finally flocculate, the value of a at the point of flocculation is very high and has been arbitrarily taken to be equal to 1×10^{-4} cm. for this calculation. It can also be shown that the calculation of the ζ-potential is not appreciably affected by even a large variation of a from this value.

The value of A has been evaluated from an analysis of the potential energy curves. Identifying ψ_0 with ζ and taking ζ = 28·2 mV., $\varkappa = 3{\cdot}357 \times 10^6$ and $a = 1 \times 10^{-4}$ cm. for sodium chloride, the values of V

for different S values are calculated from equations 1, 2 and 3 for a particular value of A. A curve is drawn by plotting the values of V against S. Different curves are obtained for different values of A. According to Verwey and Overbeek[4] the transition between stable and flocculated systems is represented by the potential curve with a weak potential barrier for which the top coincides with the horizontal axis. Therefore the value of A for which the maximum of the potential energy curve just touches the S-axis represents the value of A for this particular sol. The value of A evaluated from the graph is found to be $3{\cdot}884 \times 10^{-13}$. In the evaluation of A by the above method it has been assumed that the measured ζ-potential of the coagulum in presence of 0·0103 N sodium chloride represents the true ζ-potential of the colloid particles.

After determining the value of A by the above method the ζ-potential of the flocculated particles for any other electrolyte is determined by drawing similar potential energy curves. Knowing the value of κ from equation 4 and taking $A = 3{\cdot}884 \times 10^{-13}$ and $a = 1 \times 10^{-4}$ cm. a total potential energy curve is drawn for a particular value of ζ. Different curves are obtained for different values of ζ. The value of ζ for which the maximum of the total potential energy curve just touches the S-axis represents the ζ value for this particular electrolyte. The ζ values evaluated by this process for different electrolytes are given in column 5 of Table 1.

The ζ values evaluated from the potential energy curves are found to be very close to the ζ values obtained by electro-osmotic measurements. The above agreement between the experimental and calculated ζ values give direct support to Verwey and Overbeek's theory.

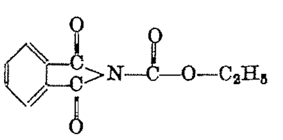
Synthesis of Phthaloyl Amino-Acids under Mild Conditions

THE synthesis of phthaloyl amino-acids, using amino-acids as starting material, often proceeds under rather drastic conditions[1]. Phthaloyl amino-acid esters, however, can be prepared under less drastic conditions[2–4]



We found that N-carboethoxy phthalimide is an excellent reagent for the preparation of phthaloyl amino-acids under mild conditions. The reaction, which is carried out in aqueous solution at room temperature, applies to many functional groups

The reagent is easily prepared from potassium phthalimide and ethyl chlorocarbonate in dimethyl formamide or from phthalimide, triethylamine and ethyl chlorocarbonate in the same solvent. It is easily crystallized from ethanol or isopropyl alcohol.

To 30 ml. of water (temp. 17°–20°) 1·5 gm. of glycine (0·02 mole), 5·75 gm. sodium carbonate 10 aq. (0·02 mole) and 4·5 gm. of N-carboethoxy phthalimide were added. The mixture was stirred for about 15 min. The solution was then filtered and the filtrate acidified. After crystallization from water and drying, 3·72 gm. of phthaloyl glycine (yield: 90·5 per cent) m.p. 191° were obtained.

With only small modifications of the above-mentioned procedure, the compounds presented in Table 1 were prepared

Table 1

Compound	Yield	m p
Phthaloyl-β-alanine	91 per cent	152°
Phthaloyl-L-glutamic acid	65 per cent	160°
Phthaloyl-DL-serine	95 per cent	152°
Phthaloyl-L-asparagine	85 per cent	199°
Phthaloyl-DL-phenylalanine	90 per cent	178°
ε-phthaloyl-L-lysine*	85 per cent	232°
Phthaloyl-DL-methionine	96 per cent	102°
Diphthaloyl-L-cystine	92 per cent	120°
Phthaloyl-L-leucine	92 per cent	110°

* Prepared from the copper complex of lysine

Phthaloyl-L-glutamic acid prepared by this method has the same rotation as reported by Clark-Lewis and Fruton[5]. After removing the phthaloyl groups in diphthaloyl-L-cystine, the cystine thus obtained (without further purification) in a yield of 85 per cent has the same rotation as our starting material, 208° in 1 N hydrochloric acid.

From these facts we conclude that the introduction of the phthaloyl group by our method respects the optical activity of the amino-acids.

Details and proposed mechanism will be published elsewhere (*Rec. Trav. Chim.*).

I would like to thank G. I. Tesser for the benefit of many discussions.

Paper Chromatography of Acidic Carbohydrates

CATIONIC detergents, such as cetyltrimethylammonium bromide ('Cetavlon') and cetylpyridinium chloride, have been used extensively in recent years for the fractionation of polysaccharide mixtures[1–4]. The quaternary ammonium cations present in these detergents form salts with acidic polysaccharides which often have solubility properties quite different from those of the usual metallic salts; for example[1], cetyltrimethylammonium chondroitin sulphate is soluble in aliphatic alcohols up to n-pentanol and is insoluble in water. Many purification procedures have utilized the water-insolubility of these quaternary ammonium polysaccharide salts, but surprisingly, no serious attempt seems to have been made to exploit their solubility in organic solvents. This communication describes some preliminary experiments directed towards developing convenient methods for the separation of acidic carbohydrates, making use of the solubility of their cetylpyridinium salts in organic solvents. Current interest in these laboratories in the purification and identification of sugar sulphates, suggested that it would be useful if this property could be utilized in a method for the paper chromatography of these substances. It has been found that when a small amount of detergent is incorporated into the mobile (organic) phase of certain solvent systems for paper chromatography, the R_F values for sulphated derivatives are increased by a factor of about ten, and some useful separations can be achieved. Two such systems are:

(*a*) *Butanol/ethanol/water* (3 : 1 : 1 *by vol.*; 100 *ml.*) *plus cetylpyridinium chloride* (3 *gm.*). The R_F values for some sugar sulphates in this solvent system are given in Table 1. The mixture obtained by the direct sulphation of glucose (with pyridine–sulphur trioxide) was resolved into at least five components (Table 1). The major monosulphated component had the same R_F value as glucose-6-sulphate, thus confirming previous results[5]. Small quantities of two other glucose monosulphates were detected, one of which had the same R_F value as glucose-3-sulphate.

Table 1. R_F VALUES OF SOME SUGAR SULPHATES*

	R_F values*	
	Solvent (*a*)†	Solvent (*b*)†
Glucose	0 21	0·18
Glucose-3-sulphate	0 67	0 85
Glucose-6-sulphate	0 41	0 77
Glucose disulphates	1 00‡	1·00‡
Products from direct sulphatation of glucose	0·21, 0 41, 0 55, 0·67, 1·00	0·18, 0·77, 0·85, 1 00

* R_F values are measured relative to the rate of movement of the slower of the two solvent fronts.

† Development period for solvent (*a*) 16 hr.; solvent (*b*) 3 hr

‡ Travels as an extremely compact zone.

(*b*) *Water-saturated methyl ethyl ketone* (100 *ml.*) *plus cetyl pyridinium chloride* (3 *gm.*). Although this solvent system is less useful than system (*a*) for the separation of isomeric glucose monosulphates, it does possess certain advantages. Thus, simple mixtures can be resolved very rapidly; for example, glucose and glucose monosulphate are well separated by a 15-min. development using the ascending technique. (Equilibration of the paper against the solvent vapour prior to development may, however, be advisable when more complex mixtures are to be analysed.) The detection of acidic sugar derivatives in a mixture (for example, a polysaccharide partial hydrolysate) should be rapid and simple since only these substances will move faster than the parent monosaccharide when the detergent is incorporated into the solvent, and slower when it is omitted.

For the location of sugar zones after irrigation of the chromatogram, two methods have been found useful. The silver nitrate–sodium hydroxide reagents[6] can be used if the paper is first rinsed with chloroform to remove the detergent, or *p*-anisidine hydrochloride[7] can be applied directly to the dried chromatogram and, after heating, the spots observed in ultra-violet light.

This work is being continued with the view of developing analogous methods for the paper chromatography of other acidic carbohydrates.

I am grateful to Mr. T. P. Williams and Mr. K. O. Lloyd for the samples of sugar sulphates used in this work, to the Department of Scientific and Industrial Research for financial assistance, and to Prof. Stanley Peat and Dr. J. R. Turvey for their interest and encouragement.

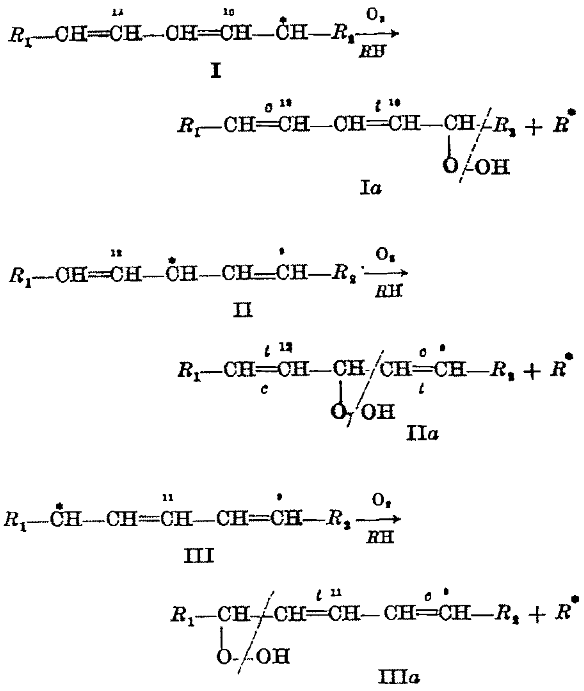
The Stereo-configuration of 2,4-Decadienals isolated from Oils containing Linoleic Acid

ACCORDING to Farmer's theory (see Bolland[1] and Bateman[2]), the following isomeric hydroperoxides (I*a*, II*a*, and III*a*) are formed in the autoxidation of linoleic acid, from the mesomeric linoleic acid free-radicals (I, II and III):



$$R_1{-}CH{=}\overset{12}{C}H{-}CH{=}\overset{10}{C}H{-}\overset{*}{C}H{-}R_2 \xrightarrow[RH]{O_2} R_1{-}CH\overset{c\ 12}{=}CH{-}CH\overset{t\ 10}{=}CH{-}\underset{O{-}OH}{CH}{-}R_2 + R^*$$

I → I*a*

$$R_1{-}CH{=}\overset{12}{C}H{-}\overset{*}{C}H{-}CH{=}\overset{\cdot}{C}H{-}R_2 \xrightarrow[RH]{O_2} R_1{-}CH\underset{c}{\overset{t\ 12}{=}}CH{-}\underset{O{-}OH}{CH}{-}CH\underset{t}{\overset{c\ \cdot}{=}}CH{-}R_2 + R^*$$

II → II*a*

$$R_1{-}\overset{*}{C}H{-}CH{=}\overset{11}{C}H{-}CH{=}\overset{\cdot}{C}H{-}R_2 \xrightarrow[RH]{O_2} R_1{-}\underset{O{-}OH}{CH}{-}CH\overset{t\ 11}{=}CH{-}CH\overset{c\ \cdot}{=}CH{-}R_2 + R^*$$

III → III*a*

R_1 = $CH_3{-}(CH_2)_4{-}$ RH = linoleic acid molecule
R_2 = $-(CH_2)_7-COOH$ R^* = linoleic acid radical
t = *trans*, *c* = *cis*.

The theoretical stereoconfiguration of the possible isomers has been indicated by Nichols *et al.*[3].

Swift *et al.*[4] have isolated from cottonseed oil (which contains approx. 45 per cent linoleic acid) in various stages of autoxidation 2,4-decadienal, 2-octenal, and hexanal. Recently, Patton *et al.*[5] have published results on the occurrence of 2,4-decadienal in several oils and fats. The formation of these decomposition products can be readily explained by means of the above-mentioned theory. From the

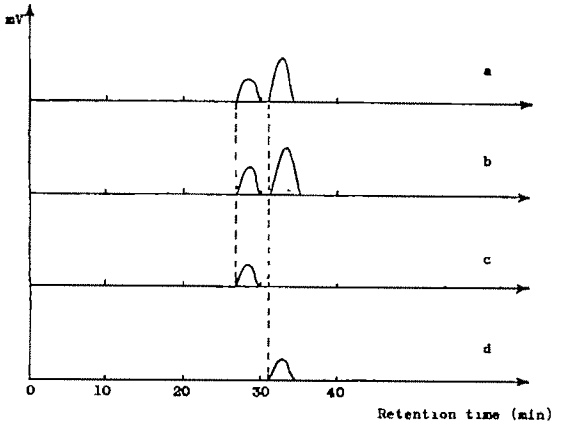


Fig. 1. Gas-liquid chromatography of. *a*, palm oil decomposition product (detail); *b*, groundnut oil, ditto; *c*, synthetic 2(*trans*)-4(*cis*)-decadienal; *d*, synthetic 2(*trans*)-4(*trans*)-decadienal Carrier, 'Celite 545'; immobile phase, silicone oil (30 per cent); mobile phase, nitrogen; pressure, 50 cm. mercury; gas velocity, 50 ml./min.; temperature, 137° C.; length of column, 90 cm.; detector, gas density balance

relevant literature, however, no information can be obtained on the stereo-configuration of the unsaturated aldehydes obtained, notably 2,4-decadienal.

From our investigations with palm oil and groundnut oil it appeared that on subjecting the volatile decomposition products to gas-liquid chromatography[6], two aldehydes could be isolated, which were identified as two isomeric 2,4-decadienals (Figs. 1*a*, *b*; 2*a*, *b*). By partition chromatography of the dinitrophenylhydrazones, following the method of Miss Kramer and van Duin[7], the 2,4-decadienal structure could be established, but not the stereo-configuration.

Two isomeric 2,4-decadienals of known stereo-configuration were synthesized. Using Brown and Subba Rao's method[8] 2(*trans*)-4(*cis*)-decadienal was prepared from 2(*trans*)-4(*cis*)-decadienoic acid. This acid was isolated, in a yield of 3–5 per cent, from *Stillingia* oil, the oil from the seeds of *Sapium sebiferum* Roxb. of which the stereo-configuration has been established by Crombie[9]. By application of Doebner's method (cf. Forss and Hancox[10]) 2(*trans*)-4(*trans*)-decadienal was synthesized, starting from hexanal. As the synthetic products and the two aldehydes isolated from volatile decomposition products gave similar results in the gas-liquid chromatographic analysis (Figs. 1*c*, *d*) and in the infra-red analysis (Figs. 2*c*, *d*), the conclusion is justified that the two natural 2,4-decadienals obtained possess the 2(*trans*)-4(*cis*) and 2(*trans*)-4(*trans*) stereo-configuration. From the gas chromatogram these *trans,cis* and *trans,trans* compounds were found to be present in the ratio of 28 : 72.

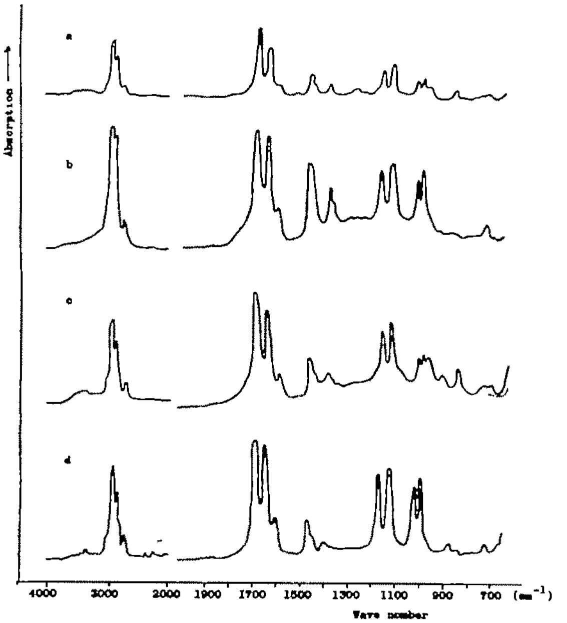

Fig. 2. Infra-red spectra of: *a*, 2(*trans*)-4(*cis*)-decadienal from palm oil (first peak in Fig. 1*a*); *b*, 2(*trans*)-4(*trans*)-decadienal from palm oil (second peak in Fig. 1*a*); *c*, synthetic 2(*trans*)-4(*cis*)-decadienal (cf. Fig. 1*c*); *d*, synthetic 2(*trans*)-4(*trans*)-decadienal (cf. Fig. 1*d*).
To record these spectra, a 'Unicam' 100, double-beam infra-red spectrophotometer was employed (rock-salt prism, microplate technique)

The above affords new, indirect proof that the (I*a*) isomer of linoleic acid hydroperoxide is formed as one of the primary autoxidation products as found spectrophotometrically by Sephton and Sutton[11]. Then it must be assumed that isomer (I*a*) serves as precursor for 2(*trans*)-4(*cis*)-decadienal. The more stable 2(*trans*)-4(*trans*)-decadienal can be formed, either as a secondary reaction product during further rearrangement of isomer (I*a*) to 9-hydroperoxy-10(*trans*)-12(*trans*)-decadienoic acid, or as a result of the instability of 2(*trans*)-4(*cis*)-decadienal. More detailed results will be published elsewhere.

We wish to thank Mr. J. H. Recourt for his assistance in carrying out the gas-liquid chromatography experiments. Further, our thanks are due to Unilever Research Department, Port Sunlight, for supplying the sample of *Stillingia* fatty acids and to the management of Unilever N.V., Rotterdam, for permission to publish these data.

Effect of Flow-Rate and Sample-Size on Column Efficiency in Gas-Liquid Chromatography

THERE have been a number of investigations as to the effect of carrier gas flow-rate on separation and column efficiency in gas-liquid chromatographic systems[1–4]. Many of the results present contradictory pictures of the effect exerted by this parameter. Keulemans[1] states, "for a certain set of operational conditions there is an optimum linear gas velocity, but the optimum is very flat and the gas rate is consequently not a highly critical parameter". James and Martin[2] have shown that column efficiency is sensitive to flow-rate and that a decrease in flow-rate increases column efficiency. Their results show a

27 per cent increase in column efficiency when the flow-rate was decreased from 24 to 10 ml./min. Bethea and Wheelock[3] reported that column efficiency, as measured by the H.E.T.P., is approximately tripled by raising the flow-rate from 5 to 27·5 ml./min. They found that increasing the flow-rate beyond the latter point gave only meagre increases in efficiency.

Mellor[4] found the critical flow-rate to be independent of temperature, pressure, column length, and load size, but dependent on column diameter and particle size of the column packing support.

During an investigation of the separation of two terpene hydrocarbons, α-terpinene and D-limonene, by means of gas-liquid chromatography, it was of interest to determine whether better separation could be achieved by selection of an optimum carrier gas flow-rate and sample size. It is a well-established fact that the efficiency of separation in a gas-liquid chromatographic column improves as the size of the sample is reduced[1,2]. Thus, with low column-load and optimum gas-flow, a high efficiency should be achieved.

The apparatus employed to separate α-terpinene from D-limonene was an 'Aerograph' model *A*-90-*C* (manufactured by Wilkins Instrument and Research, Inc., Walnut Creek, California). The column was constructed of stainless steel tubing, ¼ in. outside diameter and 10 ft. in length. The support material used was 'Sil-O-Cel' *C*-22 diatomaceous earth fire-brick (30–60 mesh). Fractions of this were sieved to size and further graded by sedimentation in water, after which they were dried at 150° for 16 hr. The liquid phase was introduced by deposition from benzene solution, the packing then being heated in a stream of helium at 150° for 16 hr.

The column was contained in an air thermostat; the carrier gas flow (helium) was controlled by a precision reducing valve and measured by a soap bubble flow meter situated at the column outlet. Temperature and flow control were sufficiently good to make possible the use of a four-channel, hot-wire katharometer that proved virtually noiseless when connected with a 1 mV. recording potentiometer. Sample injection was made with a microsyringe, and the sample preheater was maintained at 150°.

Separations were carried out with the aid of a stationary liquid phase consisting of *LAC*-4-*R*777 (the succinate polyester of diethylene glycol)[5]. This material was applied to the solid support in the amount of 25 per cent w/w. Column temperature was maintained at 100°, and recorder chart speed was 30 in./hr. The column outlet was maintained at atmospheric pressure.

Flow-rates varied from 20 to 145 ml./min. of helium. Table 1 illustrates the effect of flow-rate and sample-size on column efficiency under the experimental conditions described above. The number of theoretical plates was calculated by means of the equation[5]:

$$\text{Number of theoretical plates} = 16\left[\frac{\text{Retention volume}}{\text{Peak width}}\right]^2$$

As the number of theoretical plates can vary with the nature of the component[6], a calculation was made for both peaks on each chromatogram, and the average of the two values is presented in Table 1. It should be noted that the theoretical plate values for both peaks varied in a manner similar to that displayed by the average of the two values.

With a 0·1-μl. sample load, the theoretical plate value increased 63·8 per cent when the flow-rate of the carrier gas was decreased from 145 to 45 ml./min. An additional decrease in the flow-rate to 20 ml./min. decreased the theoretical plate value 43 per cent. Employing a 0·3-μl. sample load, this same decrease in flow-rate, that is, from 145 to 45 ml./min. increased the theoretical plate value 46·9 per cent. and a further decrease in flow-rate to 20 ml./min. decreased the theoretical plate value 26·3 per cent. At a sample load of 0·5 μl. the theoretical plate value increased 25·8 per cent and then decreased 24·6 per cent in going through the same flow-rate changes. Thus at constant sample size, a plot of flow-rate versus theoretical plate value for these systems shows a pronounced maximum.

When one operates at optimum flow-rate and varies the sample size from 0·1 to 0·3 μl., the theoretical plate value decreases by 12·5 per cent. Increasing the sample size to 0·5 μl. reduces the theoretical plate value by 39·5 per cent.

Bethea and Wheelock[3] have noted that as the flow-rate is increased the optimum sample size for maximum column efficiency increases. It may be noted that the optimum flow-rate appears to shift toward 60 ml./min. at the higher column load (Table 1).

Table 1

	Flow-rate (ml./min.)	Theoretical plates		
Sample size		0·1 μl.	0·3 μl.	0·5 μl.
	20	1499	1508	1096
	30	1967	1751	1167
	45	2144	1905	1282
	60	2040	1851	1366
	[illegible]	—	—	[illegible]
	92	1592	1601	1188
	145	1309	1297	1086

Investigations of the effects of these operational parameters are being continued and will be published in the future.

Cathode-Ray Presentation of Chromatograms

FROM the results of investigations on nylon capillary columns[1], it became apparent that there were two possible applications for the capillary system. The columns could be used to produce very high efficiencies with elution times of 10–60 min., or the high efficiencies could be sacrificed and chromatograms developed in a matter of seconds, with moderate efficiencies of perhaps 5,000 or 10,000 plates. Under these conditions it was found that a chromatogram of a mixture boiling over a range of about 100 deg. C. would be developed in 60 sec., the early peaks being eluted during a period of about

0·5 sec., but it was necessary to use a high-speed recording system with time constants of the order of milliseconds. Such a performance cannot be achieved by the normal potentiometric recorder, and the oscilloscope is an obvious alternative method of presenting the chromatogram.

In addition to the improved speed of response, an oscilloscope is also cheaper to manufacture. The complete chromatographic equipment, incorporating the column, detector and ancillary equipment, could be manufactured for less than the price of a single recorder.

With such an apparatus, it would be possible to analyse a volatile mixture in a matter of seconds, and it could be used as a laboratory instrument for routine analysis. By use of an automatic injection system synchronized with the scan, it would be possible to monitor the product from a plant every minute. Another interesting application would be its use in the investigation of reaction kinetics, where the complete analysis of a volatile mixture in a matter of seconds would be a distinct advantage.

The construction of a suitable display system is comparatively easy. The results shown below were obtained from a normal television amplifier system and power supply, coupled to a 14-in. magnetically deflected cathode-ray tube coated with a phosphor having a 200-sec. persistence. The micro-argon detector devised by Lovelock was used, in conjunction with a modified impedance converter of extremely low time-response. The scan was obtained by a linear-wound potentiometer driven by a constant-speed motor. The column used was 70 ft. of 0·020 in. diameter nylon tubing coated with a total of 8 mgm. of 'Apiezon Oil *A*' as liquid phase, and was run at an inlet pressure of 9 lb./sq. in. A 100 : 1 diluting system was used on the injection, in order that a sufficiently narrow band of solute could be placed on the column[2]. The total charge on the column was about 2 μgm. and the sensitivity of the detector was of the order of 10^{-11} gm./c.c.

A photograph of the trace obtained from the analysis of a petroleum ether mixture is shown in Fig. 1. The first two peaks, *iso*-butane and *n*-butane, are just resolved, the third high peak is *n*-hexane and the last peak is methyl*cyclo*hexane. The total scan of the tube was 50 sec. The first peak, *iso*-butane, was eluted in 31 sec. measured from the time of injection, and the elution curve itself was developed over a period of 0·5 sec. *n*-Hexane was eluted in 40 sec. and *n*-heptane in 80 sec. The efficiency for *n*-hexane on this chromatogram is between 5,000 and 6,000 plates. This is not obvious because the injection is not shown, as it occurred about two-thirds of the way through the previous scan.

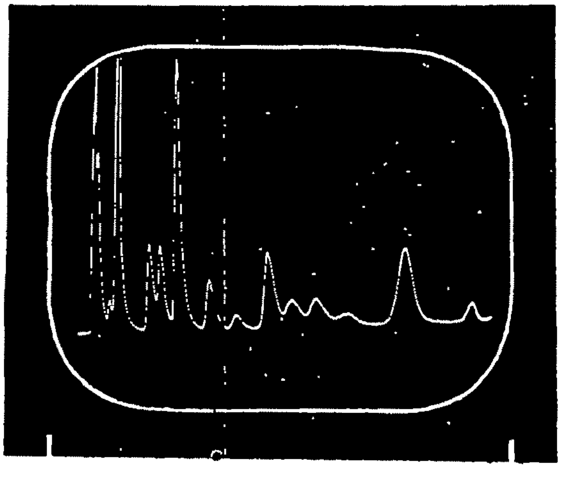

Fig. 1. Chromatogram from cathode-ray tube

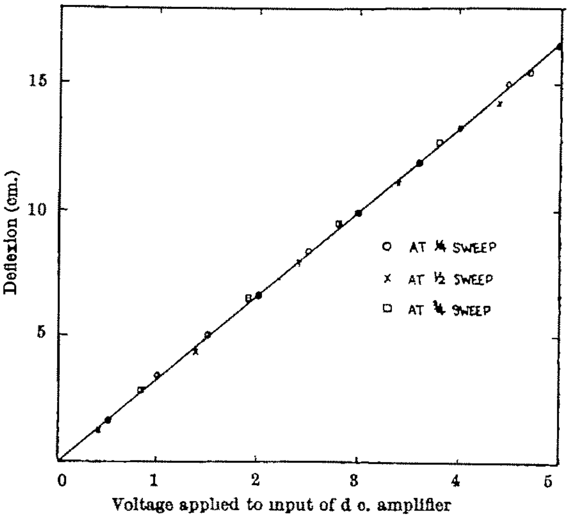

Fig. 2. '*Y* deflexion'/voltage input to d.c. amplifier

The amplifying system was adjusted to give a linear response between voltage input on the d.c. amplifier and centimetres deflexion on the *Y*-axis of the oscilloscope. Thus, providing the micro-argon detector is adjusted to give a linear response, then quantitative results can be obtained from the chromatogram. The relationship between centimetres deflexion and voltage input to the d.c. amplifier is shown in Fig. 2.

The instrument is still under development, and results have shown that higher efficiencies and even shorter times of elution are practical. However, these early results clearly indicate that the oscilloscope system is an alternative method for presenting chromatograms. Full details of this work will be published elsewhere.

BIOCHEMISTRY

Metal-Organic Complexes formed during the Treatment of Wood with Metal Salts

A RECENT communication by Belford, Cook and Nevard[1] dealt with the subject of metal-cellulose complexes formed during the treatment of Douglas fir wood with various preservative processes comprising solutions of inorganic salts or mixtures of these. The authors claim that these are formed at room temperatures, and that, in the case of the copper complex, the process by which it is formed differs from the one described by Abrams and Bottoms[2], who have also claimed the formation of a copper-cellulose complex when cellulose-containing materials, such as cotton, are treated with a solution of copper formate followed by heating.

In a study[3] of the process described by Abrams and Bottoms we have been unable to confirm the observations which led them to conclude that a copper-cellulose complex had been formed. Thus, bleached or unbleached cotton fabric treated with copper formate solution according to this method was readily dispersible in a solution of cuprammonium hydroxide of the composition normally used in dispersing textile cellulose for fluidity measurements[4]; the copper in the treated fabric could be readily leached out by dilute ammonia; the decomposition, brought about by heating, of copper formate on the bleached cotton fabric, gave the same colour change when glass fabric was used.

In a study of the kinetics of the thermal decomposition of metallic formates, Kornienko[5] found that the main products of the reaction were a metal oxide and products of the decomposition of formic acid, and that where free metal was present in the reaction products it could be attributed to the reduction of the oxides by the gaseous decomposition products, notably carbon monoxide and hydrogen. It is of interest to note that the mechanism postulated by this author would make it possible for cuprous oxide to be one of the reaction products. While the evidence from X-ray diffraction data for the presence of cuprous oxide in our fabric treated with cupric formate followed by heating is inconclusive, it does not preclude its presence.

Moreover, we found that the resistance to microbiological attack shown by cotton fabric treated with cuprous oxide was similar to that shown by the copper formate treated fabric containing a similar percentage of copper. Thus fabrics containing cupric formate and cuprous oxide at concentrations of 0·43 per cent and 0·26 per cent respectively gave essentially the same resistance in the soil burial test, namely, 6–10 per cent loss of strength for the former and 13 per cent loss for the latter.

In an earlier communication[6] Cook and Nevard refer to the copper formate process for the preservation of wood as described by Walton-Smith *et al.*[7], this being the same process described by Abrams and Bottoms[2]. Here, it is claimed by Walton-Smith *et al.* that a copper-cellulose complex is formed in the wood, and it is stated by Cook and Nevard in the article referred to above that their results prove conclusively the existence of this copper-cellulose complex. However, in the later communication[1], these latter authors give data which, they claim, indicate that the copper-cellulose complex which they believe to have been formed in their experiments is not of the same type as the one postulated by Abrams and Bottoms.

If by 'copper-cellulose complex' Cook and Nevard mean an association of copper and substantially pure cellulose we would take exception to this view, and we would suggest that the complexes formed be regarded as predominantly the product of the interaction of the metal ions with acidic, cation-binding, non-cellulose constituents of the wood. Indeed, in view of the close association of these non-cellulosic materials with the cellulose of wood, it is difficult to envisage the formation of a pure metal-cellulose complex in the amounts claimed by Cook and Nevard under the conditions of their experiments.

It is well known that 'native celluloses' show marked, but varying, tendency to take up metal cations after treatment with acid followed by washing. This effect has been examined by a number of workers and it has been shown that although a highly purified cellulose consisting substantially of α-cellulose has a small cation-binding power, relating probably to the presence of acidic end groups[8], this capacity to bind cations is greatly increased as we approach more nearly to the 'native celluloses' which are known to contain non-cellulosic constituents such as pectins, uronic acids and lignin[9].

In some of their treatments of wood with inorganic salts, Cook and Nevard observed heavy incrustations of electron-opaque material. They also observed that certain fragments of treated wood, whether showing incrustations or not, gave sharp electron diffraction diagrams, characteristic of the treatment; that in the case of copper treatments, these diagrams did not resemble any of the X-ray patterns for the copper salts employed and also that the diffraction diagram faded fairly rapidly with increasing intensity of the electron beam. All these observations are consistent with our view that the complexes formed consist of metal cations bound on the acidic groups of non-cellulosic constituents of the wood.

Such a view is also consistent with the observation of Belford, Cook and Nevard that the reaction leading to the formation of the complexes takes place at room temperature.

Mediation of the Genetic Control of Protein Synthesis in Cell-free Extracts of *Neurospora crassa*

I HAVE recently demonstrated the development of tryptophan synthetase activity by cell-free extracts from conidia of *wild-type Neurospora crassa*. The process appeared to be one of synthesis of enzyme protein, and was associated with the net increase in the protein content of the system[1]. Similar extracts prepared from the *td*$_2$ *tryptophan-less* mutant strain neither contained nor developed any detectable tryptophan synthetase activity, but did catalyse a net synthesis of protein.

The defective component of the mutant extract has been located in the 'soluble' fraction not sedimented by centrifuging at 105,000 *g* for 1 hr. As shown in Table 1, when a mutant 'particle' fraction was supplemented with *wild-type* 'soluble' fraction, considerable tryptophan synthetase activity was developed. Con-

Table 1. LOCATION OF THE GENETIC DEFECT IN EXTRACTS OF *td*$_2$ MUTANT STRAINS

Tryptophan synthetase activities (units/ml. of conidial ext.)

'Soluble' Fraction 'Particle' Fraction	Wild Type Wild Type		Mutant Mutant		Wild Type Mutant		Mutant Wild Type	
Exp. No.	Initial	Final	Initial	Final	Initial	Final	Initial	Final
1	0·21	0·37	0	0	0·21	0·30	0	0
2	0·52	0·72	0	0	0·56	0·79	0	0
3	0·20	0·37	—	0	—	0·30	—	0
4	0·30	0·47	0	0	—	0·44	0	0
5	0·17	0·34	0	0	0·19	0·30	0	0

versely, a mixture of *wild-type* 'particles' with mutant 'soluble' fraction failed to develop any detectable activity.

My method of preparing conidial extracts[1] (see below) could cause contamination by material from the cell nuclei. However, in view of the short duration of the experiments, it seems unlikely that this material contributes significantly to the development of tryptophan synthetase activity observed. Further, extracts prepared from *wild-type* mycelium by milder homogenization procedures also readily form active enzyme (unpublished results). I therefore believe that the defective component of the td_2 mutant extracts is some constituent of the cell 'sap'. Certainly, it would seem that the primary genetically determined defect in the mutant conidium is not located in the 'particulate' fraction corresponding to the microsomes of mammalian cells.

This conclusion has important implications for our understanding of the manner in which complex gene loci control the formation of specific enzymes, and of the mechanism of action of suppressor genes.

Extracts were prepared from conidia harvested from the growth on solid synthetic medium[1]. *Wild-type* cultures were grown at 30° C. for 4 days, and incubated at room temperature (about 20° C.) for a further 4 days. Mutant cultures were grown at 30° C. for 7 days on medium supplemented with 0·04 per cent (w/v) of DL-tryptophan, and incubated a further 7 days at room temperature. The washed and chilled conidia were ground with powdered glass, extracted with cold $M/20$ sodium potassium phosphate buffer (pH 6·5) containing 20 per cent (w/v) sucrose, and separated into 'soluble' and 'small particle' fractions as described in detail elsewhere[1].

The reaction system contained 'soluble' fraction, 'small particle' fraction, 4 per cent (w/v) Difco 'Bacto Casamino Acids', 6·4 mgm. L-cysteine hydrochloride, 50 mgm. hexose diphosphate magnesium salt, 4 mgm. diphosphopyridine nucleotide, 0·4 mgm. calcium chloride, $1{\cdot}26 \times 10^{-1}$ M magnesium sulphate and 42 mgm. of polyvinyl acetate (as a finely dispersed emulsion) in a final volume of 28 ml. In experiment 5 a mixture of 8 mgm. of L-proline plus 3·2 mgm. of each of L-threonine and L-valine replaced half the casein hydrolysate.

Tryptophan synthetase enzyme was precipitated from samples of the reaction system, taken before and after incubation for 1 hr. at 30° C., by a modification[1] of the procedure of Suskind and Kurek[2], and enzymic activity was assayed by a modification[1] of Yanofsky's method[3]. Total protein nitrogen was determined by standard micro-Kjeldahl techniques after precipitation with trichloracetic acid, and extraction of nucleic acids and lipids[1].

This work was supported by the National Research Council, the Connaught Medical Research Fund and the National Cancer Institute of Canada.

I am indebted to the Dupont Company of Canada, Ltd., Montreal, for a generous gift of polyvinyl acetate emulsion.

Anærobic Glycolysis of Dispersed Cell Suspensions from Normal and Malignant Tissues

IN studies of cellular metabolism, the potential advantages of using dispersed cell suspensions rather than tissue homogenates or slices have led a number of workers to investigate the methods of preparation and properties of cell suspensions from various tissues[1–5]. Liver parenchymal and kidney epithelial cell suspensions prepared by mechanical disruption of the tissue, with or without prior perfusion of the organ, appear to be morphologically intact when examined by either light or electron microscopy[1,2]. These cell suspensions, however, are apparently metabolically different from tissue slices, since they show negligible endogenous respiration which cannot be restored by glucose or a number of protein and non-protein factors[2,3], and have lost the ability to convert intracellular carbohydrate to lactic acid[3]. The oxidation of succinate by these cells, however, has been reported to proceed at a rate exceeding that observed with slices[2,3], and is independent of exogenous cytochrome c (ref. 4). Liver cell suspensions have also been found to incorporate glycine at a rate seven-fold greater than that observed with homogenates[6].

We have found that cell suspensions from a number of solid and ascitic animal tumours metabolize glucose either aerobically or anærobically, whereas isolated liver and kidney cells do not. This difference in behaviour between these normal and tumour cell suspensions was found to be due to a nearly complete loss of some of the enzymes of the Embden–Meyerhof system from the kidney and liver cells, but not from the tumours tested.

Rat liver and kidney cells were prepared by Anderson's procedure[1], namely, perfusion of the organ with calcium-free Robinson's solution containing 0·027 M citrate, followed by dispersion of the tissue in a loose-fitting homogenizer. The cells were then washed twice with calcium-free Robinson's solution. Cells from solid tumours were prepared in the same fashion, except that the tissues were dispersed without prior perfusion; ascites cells were diluted with the perfusion medium and washed as above. The yield of intact cells varied with source of tissue, but was in close agreement with published results[1]. Suspensions of dispersed cells from the solid Novikoff hepatoma and both the Novikoff and Ehrlich ascites tumours were found to grow at a rate equal to, or better than, untreated tumour mince, or whole ascites fluid, respectively, when transplanted, indicating no loss of viability during isolation.

The lack of respiration of liver and kidney cells in an unfortified system with or without glucose was con-

Table 1 ANÆROBIC GLYCOLYSIS OF CELL SUSPENSIONS

The reaction system (3·0 ml.) contained 7·5 μmoles phosphate (pH 7·4), 20 μmoles magnesium chloride, 49·5 μmoles potassium bicarbonate, and 150 μmoles potassium chloride; 1·0 μmole adenosine diphosphate (ADP), 1·0 μmole diphosphopyridine nucleotide (DPN), and 50 μmoles glucose where indicated. The vessels were gassed with 95 per cent nitrogen–5 per cent carbon dioxide for 10 min. Incubation, 1 hr. at 30° C. The values are μmoles lactic acid/hr./mgm. nitrogen.

Tissue	Minus ADP and DPN Endogenous	Minus ADP and DPN + Glucose	Plus ADP and DPN Endogenous	Plus ADP and DPN + Glucose
Liver	0	0	0	0
Kidney	0	0	0	0
Thymus	0·2	2·0	0·9	2·2
Novikoff hepatoma (solid)	0·3	2·0	0·9	5·0
Murphy lymphosarcoma	0·3	4·4	0·3	4·6
Walker-256	0·3	1·5	0·8	4·6
Gardner lymphosarcoma	0·7	5·3	0·9	8·0
Novikoff hepatoma (ascites)	0·8	4·6	1·0	5·5
Ehrlich ascites	0·5	5·6	0·6	6·0

firmed, whereas tumour cell and thymocyte suspensions show both endogenous and glucose-stimulated respiration. Succinate was oxidized by all cell suspensions studied, and the rate could be stimulated by addition of adenosine diphosphate. Preliminary results of a study of the oxidation of a variety of substrates by these cell suspensions indicate that adenosine diphosphate and diphosphopyridine nucleotide are required for maximal activity.

The results of a comparison of anærobic glycolysis by cell suspensions from various tissues are shown in Table 1. Liver and kidney cells did not catalyse anærobic glycolysis, as measured in terms of lactic acid production/hr./mgm. nitrogen from glucose. There was, however, a small but measurable release of carbon dioxide when measured manometrically. Fortification of the medium with adenosine diphosphate and diphosphopyridine nucleotide did not restore the glycolytic ability of these cells, indicating that the metabolic alteration was not caused by leakage of these co-factors. No activity could be demonstrated using the system described by LePage[7], which was designed to demonstrate glycolysis with homogenates of normal tissues. Thymocytes and all the tumours tested catalysed an active glycolysis, both from endogenous substrates and glucose, which could be stimulated by adenosine diphosphate and diphosphopyridine nucleotide with some tumour cell suspensions.

The inability to produce lactic acid from glucose in liver and kidney cells has been demonstrated to be due to the loss of at least two key enzymes of the glycolytic pathway. In Table 2 the specific activity of aldolase and lactic dehydrogenase of the original dispersed tissue, prior to centrifugation, and the final washed-cell suspension are compared, since measurements of total activity in the fractions are not significant due to variations in the yield of cells from the various tissues. Isolated liver and kidney cells contained negligible aldolase and lactic dehydrogenase, whereas cells from thymus and the tumours retained a significant quantity of both enzymes. The enzymes lost from the normal cells were quantitatively recovered in the wash fluids. Glycerophosphate dehydrogenase has also been found to be completely leached out of the liver and kidney cells. This leakage of enzymes has been demonstrated with liver and kidney cells prepared by other techniques for dispersal[4,5]. Perfusion with various media (for example, serum albumin in saline, whole serum, tissue culture medium 199 and mouse ascitic fluid all containing citrate) did not yield cells which retained these enzymatic activities. Cell suspensions from all solid tumours with the exception of the Murphy lymphosarcoma, which requires drastic treatment for dispersal, retained the greater part of their initial content of these enzymes, as shown by a comparison of the specific activity of the dispersed tissue fraction and the washed cell suspension.

Table 2 ALDOLASE AND LACTIC DEHYDROGENASE ACTIVITY OF TISSUE HOMOGENATES AND CELL SUSPENSIONS

Aldolase activity was determined essentially by the method of Dounce *et al.* (ref. 8). Specific activity equals change in optical density (540 mμ) per mgm. nitrogen of chromogen formed in 15 min. Lactic dehydrogenase determined spectrophotometrically; specific activity is μmoles reduced diphosphopyridine nucleotide oxidized/min./mgm. nitrogen, measured as the initial rate. Values are the average of three experiments

Tissue	Aldolase activity Dispersed tissue*	Aldolase activity Cells	Lactic dehydrogenase Dispersed tissue*	Lactic dehydrogenase Cells
Liver	3·8	0·1	8·6	0
Kidney	3·2	0·1	2·0	0

Novikoff hepatoma (solid)	3·5	2·7	3·5	2·5
Murphy lymphosarcoma	11·7	4·1	3·1	1·8
Walker-256	8·8	4·8	6·0	3·2
Gardner lymphosarcoma	5·2	3·6	3·4	3·6
Novikoff hepatoma (ascites)	6·3†	13·6	4·9†	12·1
Ehrlich ascites	4·2†	4·9	5·4†	8·7

* Tissue after dispersion but prior to centrifugation.
† Total ascites fluid and cells.

Although appearing morphologically intact, liver and kidney cell suspensions have been demonstrated not to be biochemically 'intact' due to the complete loss of some soluble enzymes. The use of such cell suspensions for certain metabolic studies is thus limited. The differential leakage of some enzymes from cell suspensions of malignant tissues and thymus as compared with liver and kidney suggests a fundamental difference in the membrane structure of cells depending on the degree of organization of the tissue source.

Spectrophotometric Determination of Tryptophan by the Method of Roth and Schuster: Some Sources of Error

IN Roth and Schuster's method[1] for colorimetric determination of tryptophan in vegetable matter, the measurement of the yellow colour is made with a Pulfrich Stufenfotometer with filter *S* 43. The method has often been used, but I have been unable to find any published account of the measurements made spectrophotometrically. I have therefore tested the method for some cereals, etc., by means of a Beckman spectrophotometer, model *D.U.*

It appeared that the absorption curves for the yellow compounds produced by D,L-tryptophan and the vegetable matter, respectively, have the same form only within a limited range of wave-lengths. In preliminary attempts to account for this, it was observed that nitric oxides developed during the process of nitration (especially in the case of substances rich in carbohydrates) are dissolved in the reaction mixture, to which they impart a yellow colour. Furthermore, it was found that lignin, which occurs in lignified vegetable matter, is nitrated, forming vividly yellow compounds, and the determination is thus distorted.

The effect of the nitric oxides was shown by the difficulty of obtaining reproducible determinations. The following experiment showed that the nitric oxides contributed to producing the yellow colour: the reaction mixture was bubbled with nitrogen dioxide at room temperature until the air above the fluid assumed a reddish-brown colour from nitric oxides. Dilutions of the solution showed that as little as 1/16 of the original quantity of nitrogen dioxide gave a measurable extinction at 450 mμ.

The occurrence of nitric oxides in the solutions for analysis can be shown by testing for nitrite (development of a red colour by diazotization of sulphanilic acid and coupling in alkaline fluid with α-naphthol), as nitrous acid develops in the solutions:

$$2\,NO_2 + H_2O \rightleftarrows HNO_2 + HNO_3$$

The nitric oxides could be removed completely by sucking air vigorously through the filtered solutions to be analysed. The procedure only caused a slight change of the extinctions (2 per cent), for which correction can be made.

The solutions for analysis (wheat grain, wheat straw) contained nitrogen dioxide corresponding to $\frac{1}{2}$–$\frac{1}{8}$ of the nitrogen dioxide test solution.

The absorption curves for the nitrated solutions of D,L-tryptophan show a maximum at 330–340 mμ. The extinction curves for the wave-lengths of 380, 400, 420, and 450 mμ (1–10 mgm./50 ml., 1 cm. cuvettes) and 400, 410 . . . 500 mμ (5-cm. cuvettes) were all straight lines.

Samples of grain (wheat, oats, rye, barley) and proteins (gluten, albumen) on nitration yielded yellow products, the absorption curves of which for wave-lengths up to about 440 mμ were steeper than those for tryptophan, while for the range 440–500 mμ they followed those of tryptophan, indicated by the fact that the extinctions here, calculated as tryptophan, yielded the same values.

For hulls of oats and for wheat straw the results were different. On nitration they left orange-coloured precipitates, which could only with difficulty be rinsed free from colour. The solutions showed greater absorption in the range of about 470–500 mμ than tryptophan (crossing of the tryptophan curve). The extinction at 450 mμ, calculated as tryptophan, yielded unusually high values. For wheat-straw (0·5 gm. sample) a tryptophan content of 2·25 per cent was found, corresponding to 25·3 per cent tryptophan in the protein (nitrogen × 6·25).

On going through groups of substances which might be supposed to give rise to the formation of yellow-coloured nitration products, lignin attracted special attention, as this is of an aromatic character and is found in lignified vegetable matter, such as the straw and hulls of grain.

Further evidence was obtained by treatment of samples of lignin (acid-lignin). On nitration, compounds of a vividly yellow colour developed, the absorption curves of which showed the crossing of the tryptophan curve characteristic of wheat straw and oats hulls. At 450 mμ a quantity of 0·01 gm. lignin gave the same extinction (0·102) as 1 mgm. tryptophan (0·105), and Roth and Schuster's method therefore in its present form must be considered unsuitable for vegetable matter with even a slight content of lignin.

Curve *A*, nitrogen dioxide dissolved in reaction mixture; curve *B*, 1·5 gm. wheat grain; curve *C*, 1·0 gm. oats straw; curve *D*, 0 1 gm. lignin. The solutions were diluted to 50 ml. before being measured

As to other kinds of vegetable matter, etc., it is necessary to undertake the measurements at a wave-length higher than about 440 mμ, which necessitates the use of 5-cm. cuvettes. However, it will be desirable to investigate the character of compounds which cause increased absorption below about 440 mμ, as the possibility cannot be precluded that some of the absorption above 440 mμ originates from this.

Roth and Schuster have thoroughly tested a number of amino-acids, etc., with a view to the development of yellow-coloured compounds. The absorption spectra of these have been examined in this Department; a few of them (especially tyrosine, phenylalanine and methionine) showed absorption. The character of the compounds formed is under investigation.

The acid-lignin used has kindly been placed at our disposal by Dr. N. E. Warburg, Køge.

Antibodies in Ribonucleoproteins

IN many hypotheses concerning the mechanism of the immune response the nucleic acids have been assigned a role in the production of antibodies, although no clear evidence for their participation is yet available. As regards protein synthesis in general, there is reason for believing that the ribonucleoproteins lie in the pathway of this synthetic process[1]. Evidence also exists that certain enzymes are present in the ribonucleoprotein complex[2,3], and it is possible that they represent products of protein synthesis mediated by ribonucleoprotein. The present communication describes an attempt to ascertain whether antibodies also are present in ribonucleoprotein complexes isolated from the antibody-forming organs, spleen and lymph nodes, of the rabbit.

Evidence that ribonucleoprotein may be involved in antibody production has already been presented by Sterzl and Hrubesova[4] and Hrubesova *et al.*[5].

They have shown that infant rabbits, still unable to synthesize antibodies, acquire this ability when injected with crude 'nucleoproteins' obtained from the spleens of immunized adult rabbits. The 'nucleoproteins' used in this important and suggestive work were, however, very heavily contaminated with extraneous protein. Furthermore, it is difficult to distinguish between the contribution of donor and recipient animal in this type of experiment. We have therefore employed more highly purified ribonucleoprotein preparations and have attempted an *in vitro* demonstration of antibodies.

The experiments were carried out in the following way. Immunized rabbits (together with several non-immunized control animals) were killed when they showed a high level of serum antibodies. The spleens and sometimes the lymph nodes were removed and used for the isolation of ribonucleoprotein. It was generally found that these organs were larger and heavier in the immunized animals than in the controls.

The isolation of ribonucleoprotein was carried out in a cold room, and a buffer containing 0·002 *M* magnesium sulphate and 0·001 *M* *tris*(hydroxymethyl)aminomethane, *p*H 7·1, was used throughout. Microsomes were prepared from homogenized tissues by a low- (10,000*g*, 30 min.) and a high- (105,000*g*, 2 hr.) speed centrifugation. The microsomes were disrupted with 0·75 per cent sodium deoxycholate, and ribonucleoprotein particles were isolated by two further cycles of high- and low-speed centrifugation[6]. The ribonucleic acid content of the purified material was determined as described elsewhere[5]. As weight per cent of ribonucleic acid plus protein it amounted to about 30–40 per cent for the spleen ribonucleoprotein and 45–50 per cent for the lymph node particles. In nearly all cases the yield of ribonucleoprotein per unit weight of organ was higher for the immunized than the control animals.

Portions of the ribonucleoprotein were digested with pancreatic ribonuclease (1–3 μgm./ml.) under dialysis against several changes of 0·15 *M* sodium chloride at 37° for 5–6 hr., followed by an overnight dialysis in the cold. This treatment removed virtually all the ribonucleic acid. Although the bulk of the protein coagulated, a certain proportion remained soluble. After removal of the coagulum by centrifugation, the soluble protein derived from the degraded nucleoprotein was tested for the presence of antibodies. A number of such tests were also made with undegraded ribonucleoproteins.

In most of our experiments the antigen was sheep red blood cells and the tests were made only with spleen ribonucleoprotein. In these cases the animals were immunized with 1 ml., respectively, of a 30 and 15 per cent suspension of red blood cells injected intravenously six days apart. Six days after the second injection the serum antibody titres of these animals and of the controls were determined, the spleens were removed, and ribonucleoprotein was isolated. The serum titre of the immunized animals was generally of the order of 2^{10}. Direct tests for the presence of agglutinins were made by incubating serial dilutions of either the intact ribonucleoprotein or the soluble protein fraction in physiological saline at 37° with 1 per cent suspensions of the antigen.

No trace of agglutinins was detected in the intact ribonucleoprotein, whether from non-immunized or immunized animals. When, however, the soluble protein fraction derived from the degraded ribonucleoprotein of immunized animals was tested, a typical agglutinin reaction was observed, with titres up to 2^4. In contrast, the soluble proteins from the non-immunized controls caused no agglutination. Thus, antibodies appear to have been present in the spleen ribonucleoproteins of the immunized animals. Their immunological reactivity was apparently not expressed until the ribonucleoprotein was degraded, at which time, presumably, the antibody would be liberated from the nucleoprotein complex.

In view of the low agglutinin titres found in the direct tests, the soluble protein fractions were also subjected to the more sensitive Coombs test. Here, 3 per cent suspensions of sheep erythrocytes (in 0·14 *M* sodium chloride buffered at *p*H 7·1 with 10^{-3} *M* *tris*(hydroxymethyl)aminomethane) were incubated with the soluble proteins for 90 min. at 37°, were washed with buffered saline, and were tested against two times serial dilutions of sheep anti-rabbit serum ('Wellcome' sheep precipitating serum). Those erythrocytes which had been incubated with the soluble ribonucleoprotein proteins of immunized animals were completely agglutinated, being shown thereby to be coated with rabbit antibodies. The Coombs reaction gave a titre of 2^9, with a pro-zone of 2–3 dilutions. Again, the non-immunized controls gave negative tests.

In another experiment non-agglutinating antibodies were tested for. Horse serum globulins, mixed with Freund adjuvant, were injected subcutaneously into rabbits. Nine days later, when the serum titre >3125, spleen and lymph node (inguinal, axillar and brachial) ribonucleoproteins were prepared and degraded with ribonuclease. As noted above, the yield of ribonucleoprotein per unit weight of organ was markedly greater for the immunized than for the non-immunized animals (1·09 vs. 0·53 mgm./gm. of lymph node tissue). Direct interfacial ring tests of the soluble protein fractions gave negative results. Tests were then made with Stavitsky's modification[7] of Boyden's method, wherein the antibody agglutinates antigen-coated sheep erythrocytes (tanned at 37°, sensitized with antigen by exposure to horse serum at room temperature, washed and suspended in a hundred times diluted complement-inactivated (56°, 30 min.) non-immune rabbit serum).

The results (Table 1) show that antibodies were present in the soluble protein fraction derived from the lymph node ribonucleoprotein of immunized animals. The absence of detectable antibodies in the spleen ribonucleoprotein is of doubtful significance, owing to the possibility that the subcutaneous immunization had caused the nodes to be activated earlier than the spleen and to have undergone a more intense response at the time of organ extirpation.

Although the experiments described here are still in a preliminary stage, they indicate that the process of antibody response involves a marked increase in the ribonucleoprotein content of the antibody-

forming organ, and that the protein moiety of this ribonucleoprotein contains antibodies which are released in an active form upon the destruction of the ribonucleic acid moiety. These observations are consistent with the concept that the antibody molecule forms part of the ribonucleoprotein complex within the antibody-producing cell, and that this complex may, therefore, be the site of its synthesis Similar observations have been made in the case of the release of the enzymes ribonuclease and deoxyribonuclease from a bacterial ribonucleoprotein[2], and it is possible that this is a general phenomenon of protein biosynthesis.

This investigation was supported in part by a research grant (*RG*-5876) from the National Institutes of Health, U.S.A. Public Health Service.

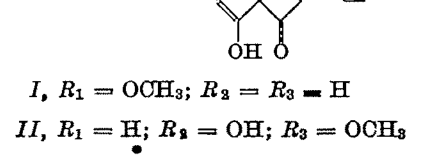
Flavonoids of the Ponderosa Lemon

THE isolation and structure of citronin, a new flavanone glycoside from the peel of immature Ponderosa lemons (*Citrus limon* Burm. *f. ponderosa* Hort.) was reported some time ago by Yamamoto and Oshima[1]. From chemical and spectroscopic evidence it was concluded that citronin is 2′-methoxy-5,7-dihydroxyflavanone 7-rhamnoglucoside (*I*) and thus belongs to the rather uncommon group of flavonoids having a substituent at position 2′. In attempting to obtain this compound from samples of both mature and immature Ponderosa lemons, under conditions approximating those of Yamamoto and Oshima, it has been our experience that the only glycoside which can be isolated easily in crystalline form is neohesperidin (*II*). This was identified by elementary analyses, mixed melting point determination, infra-red spectrum, preparation of the phenylhydrazone derivative and isolation of the aglycone hesperetin from the hydrolysate. Neohesperidin differs from hesperidin only in the position of attachment of rhamnose to glucose[2]:



$$I,\ R_1 = OCH_3;\ R_2 = R_3 = H$$

$$II,\ R_1 = H;\ R_2 = OH;\ R_3 = OCH_3$$

The isolation of neohesperidin from the Ponderosa lemon is of interest for several reasons. First, as Swingle has pointed out[3], "the nature of the characteristic glucoside present in the tissues of a species of *Citrus* may be of definite taxonomic significance in distinguishing that species from another species to which it may have superficial resemblances". The Ponderosa is generally considered to be in the nature of a hybrid which most nearly resembles the lemon (*Citrus limon*), but it is also regarded as having certain characteristics of the citron and grapefruit[4]. Ordinary lemons have not been shown to contain neohesperidin, but do contain hesperidin, diosmin[5] and eriodictyol glycoside[6] as their principal flavonoids. From qualitative tests, we consider that the Ponderosa lemons used in the present work contained little if any hesperidin or eriodictyol glycoside. Therefore, to judge from the identity of the most abundant and easily detectable flavonoids, the Ponderosa lemon would seem to have little relation to ordinary lemons. It is noteworthy that neohesperidin has been found previously only in the sour orange (*Citrus aurantium*)[7] and trifoliate orange (*Poncirus trifoliata*)[8].

Secondly, although it would be unwarranted to suggest that citronin is identical with neohesperidin (since there appear to be several irreconcilable points of difference), it should be noted that some of the chemical evidence reported by Yamamoto and Oshima is incompatible with their structure *I*. According to these authors, citronin (*a*) gives no ferric colour; (*b*) gives *o*-hydrocoumaric acid methyl ether when cleaved with alkali; and (*c*) after hydrolysis to its aglycone gives 5,7,2′-trimethoxyflavanone on treatment with diazomethane. On the contrary, compound *I* or its aglycone would unquestionably give a ferric colour; would be expected to yield *o*-coumaric acid methyl ether (rather than the hydrogenated derivative); and would undergo methylation at the 5-position very slowly, if at all, by means of diazomethane. In fact, some of the evidence suggests that citronin might conceivably be a dihydrochalcone similar to phloridzin.

Finally, it should be mentioned that botanical variations might account for the difference in the results of Yamamoto and Oshima and ourselves. Dr. W. P. Bitters has pointed out to us that there are two forms of the Ponderosa lemon, one of American origin (used in the present work) and the other of Javanese origin, which are undoubtedly of slightly different genotypes but of very similar phenotypes.

We should like to thank Dr. Bitters and Dr. W. B. Sinclair of the Citrus Experiment Station, University of California, Riverside, for their kindness in providing us with authentic Ponderosa lemons.

An Elastin Gel

THE present report describes the conversion of insoluble aorta elastin to a gel. Wood[1] recently described the preparation of an elastin gel from a soluble protein derived from cattle ligamentum nuchæ. These observations may have some bearing on the relationship between collagen and elastin[2-5].

Elastin was prepared from cattle aorta by a method described previously[6], in which 1 *N* sodium hydroxide is used for removing collagen. (Some cattle aorta do not yield insoluble elastin under these severe conditions, perhaps owing to their age.) For the preparation of the gel, the elastin was suspended at room temperature in a 0·1 per cent solution of elastase, in acetate buffer at *p*H 4·7 and ionic strength 0·1. (Two different elastase preparations were used: a lyophilized water extract of porcine pancreatin and porcine elastase *PI*[6].) After at least 10 min., the suspension was centrifuged and the residue washed with the buffer. The washed residue was then suspended in 10 vol. of 0·2 *N* acetic acid, from which, on standing, the gel formed.

Gel formation does not occur when (*a*) cattle ligamentum nuchæ is the elastin source; (*b*) cattle aorta elastin is boiled in 0·1 *N* sodium hydroxide; or (*c*) the enzyme treatment is omitted.

The gel melts upon either warming or adding sodium chloride, with subsequent formation of an elastin precipitate. An approximation of the melting point can be made by suspending 1 vol. of packed gel in 5 vol. of aqueous solvent and noting the temperature at which flocculation begins. As the concentration of sodium chloride of the suspension medium increases from 0·01 *M* to 2·0 *M*, the melting and precipitation point first rises and then falls, the maximum occurring between 0·05 and 0·5 *M* sodium chloride. Syneresis has never been observed, even after prolonged storage at 4°C., in the absence of salt.

PHYSIOLOGY

Experimentally Induced Proliferation of the Rudimentary Gonad of an Intact Domestic Fowl

IT is well known that the right female gonad of the domestic fowl ceases to grow about the ninth day of incubation and that it always hypertrophies following sinistral ovariectomy. I have shown[1] that œstrogen could act *in vivo* as the inhibitor of rudiment growth. In view of the anti-œstrogenic effect of 17 α-ethyl-19-nortestosterone ('Nilevar', Searle) upon the chicken's oviduct[2], the effect of this substance upon the rudimentary chicken gonad was investigated. Starting at 60 days of age intact White Leghorn females received 40 subcutaneous injections of 'Nilevar'. The substance was dissolved in a carrier of 5 per cent benzyl alcohol in corn oil and 0·1 c.c. of solution was injected daily. Experimental procedures were analogous to those outlined in the earlier paper[1] and the weights of blotted, fixed (Bouin's fixative) tissue were recorded (Table 1).

Table 1

No. of birds	Treatment	Rudiment weight (mgm.) at 100 days ± standard error of the mean
9	Carrier . ..	5 ± 1
10	1·5 mgm. 'Nilevar'/day	13 ± 1
8	3·0 mgm. 'Nilevar'/day	20 ± 2

Statistical analysis showed the differences due to treatment to be highly significant.

This is the first report of experimentally induced proliferation of the rudimentary intact fowl gonad. Detailed results, including evidence that the proliferation is due to the anti-œstrogenic action of 'Nilevar', will be published elsewhere.

Effect of Testosterone Propionate and Insulin on Muscle Cholinesterase Activity

VARIOUS hormones influence the cholinesterase activity of tissues[1,2]. The purpose of the present work was to investigate the influence of some anabolic hormones such as testosterone and insulin on muscle cholinesterase activity.

Muscle cholinesterase was studied on male albino rats weighing 250 gm. and kept on a standard stock food. The animals were divided into three groups. One group received 1 mgm. testosterone propionate in 0·2 c.c. sesame oil per animal for ten days, the second group 2 I.U. of crystalline insulin per kgm. body-weight for the same period. The third group was used as control. The animals were autopsied 24 hr. after the last injection, and the cholinesterase activity was determined in diaphragm and gastrocnemius in tissue homogenates by Michel's method[3]. The results (Table 1) are expressed in Δ *p*H/hour per gm. of wet tissue weight.

Table 1. EFFECT OF TESTOSTERONE PROPIONATE AND INSULIN ON RAT'S GASTROCNEMIUS AND DIAPHRAGM CHOLINESTERASE

	No. of animals	Gastrocnemius	Diaphragm
Control	24	0·783 ± 0·068	0·910 ± 0·070
Testosterone propionate (1 mgm. per day)	12	1·410 ± 0·110 ($P < 0{\cdot}01$)	1·065 ± 0·050 ($P < 0{\cdot}05$)
Insulin (2 I.U. per kgm. body-weight per day).	12	1·157 ± 0·048 ($P < 0{\cdot}01$)	1·204 ± 0·064 ($P < 0{\cdot}05$)

The cholinesterase activity is expressed in Δ *p*H/hour per gm. of wet tissue. The determinations were carried out on 0·2 gm. wet tissue.

As is seen in Table 1, testosterone propionate produces a significant increase in cholinesterase activity of gastrocnemius ($P < 0{\cdot}01$) and a rather moderate increase in diaphragm cholinesterase activity

($P < 0.05$). Insulin has virtually the same effect (Table 1). An increase in muscle cholinesterase activity is also observed during embryonic development where marked anabolism occurs[4]. Therefore a relationship is suggested between anabolism and cholinesterase activity in striated muscles. The above results seem to support such a hypothesis since testosterone has a well-known myotropic effect[5] and insulin is also considered as an anabolic agent[6].

Assaying Luteinizing Hormone

THERE is a demand for an easy and accurate method of assaying the luteinizing fraction of gonadotrophic hormone. The present method depends upon the formation of corpora hæmorrhagica in the ovaries of immature female mice after rendering their Graafian follicles mature. The gonadotrophic materials used were pregnant mare serum ('Antex', Leo) as a source of follicle stimulating hormone, and chorionic gonadotrophin ('Physex', Leo) as a source of luteinizing hormone. The material used for assay was dissolved immediately before use in sterile saline and administered as a single dose to avoid deterioration of the hormone by storage even when refrigerated[1].

Table 1. INFLUENCE OF DOSE OF PREGNANT MARE SERUM ON THE CORPUS HÆMORRHAGICUM RESPONSE

Dose of PMS (I.U.)	Dose of HCG (I.U.)	No. of animals	Average No. of corpora hæmorrhagica/mouse*
20	None	15	0·20 ± 0·03
20	10	15	3·66 ± 0·26
40	None	15	0·28 ± 0·07
40	10	15	3·86 ± 0·10
80	None	15	0·30 ± 0·03
80	10	15	3·43 ± 0·36

* ± Standard error.

In order to determine the dose of pregnant mare serum and the time after its administration when the Graafian follicles become fully developed and ready for ovulation, 90 immature female Swiss mice, 3–4 weeks old, were used. They were divided into 3 groups which were injected subcutaneously with a single dose of either 20, 40, or 80 I.U. of pregnant mare serum. The number of animals with opened vaginas were counted daily. On the fourth day there were more than 80 per cent of these. Half the animals of each group were injected subcutaneously with a single dose of 10 I.U. of chorionic gonadotrophin and vaginal smears were taken daily. Forty-eight hours after administration, all smears were either metœstrus or diœstrus. The animals were killed with ether, their ovaries dissected, and the number of corpora hæmorrhagica formed in both ovaries of each animal was recorded.

After establishing the time relations of the assay method, 4 runs of assay were planned. Two assays were run together. In one case the initial dose of pregnant mare serum was 40 I.U. and in the other 20 I.U. After four days the animals were given graded doses of chorionic gonadotrophin as shown in Table 2. The third assay was planned to determine if variations in the follicle-stimulating hormone/luteinizing hormone ratio would influence the slope of the regression line and if it induces a source of error in the assay. 4 days after the injection of 20 I.U. of pregnant mare serum as usual, a total dose of 25 I.U. of different combinations of pregnant mare serum and chorionic gonadotrophin were injected as presented in Table 3. The assay No. 4 was performed to test if blood serum could modify or augment the corpus hæmorrhagicum response to luteinizing hormone as happens in other methods[2]. A comparison was made between the corpus hæmorrhagicum response to 10 I.U. of chorionic gonadotrophin dissolved in saline with that dissolved in ox serum (Table 4).

Table 2. CORPUS HÆMORRHAGICUM RESPONSE TO GRADED DOSES OF CHORIONIC GONADOTROPHIN

Dose of HCG (I.U.)	Average No. of corpora hæmorrhagica 40 I.U. PMS	20 I.U. PMS*
None	0·28 — 0·07	0·33 ± 0·10
1	2·86 — 0·09	3·28 ± 0·33
10	4·86 — 0·48	5·83 ± 0·28
100	8·93 — 0·85	9·83 ± 0·84
1,000	—	9·25 ± 0·98

* ± Standard error. Each group contained 7 mice.

Table 3. INFLUENCE OF FOLLICLE STIMULATING HORMONE/LUTEINIZING HORMONE RATIO ON CORPUS HÆMORRHAGICUM RESPONSE

Dose of PMS (I.U.)	Dose of HCG (I.U.)	Average No. of corpora hæmorrhagica
None	None	0·33 ± 0·05*
5	20	6·00 ± 0·28
10	15	5·00 ± 0·33
15	10	4·50 ± 0·38
20	5	3·80 ± 0·36

* ± Standard error.
Each group contained 7 animals.
All mice were previously treated with 20 I.U. of PMS.

Table 4. INFLUENCE OF ADDITION OF SERUM ON THE CORPUS HÆMORRHAGICUM RESPONSE

Treatment	Average No. of corpora hæmorrhagica*
0·5 ml. ox serum	1·25 ± 0·12
10 I.U. of HCG + 0·5 ml. ox serum	5·00 ± 0·86
10 I.U. of HCG + 0·5 ml. saline	4·75 ± 0·12

* ± Standard error.
Each group contained 8 animals.
The animals were previously treated with 20 I.U. PMS.

The average of the number of corpora hæmorrhagica formed in an animal was plotted against the logarithm of the dose. This dose response curve showed a straight line, up to 100 I.U. of chorionic gonadotrophin. The slopes of the response curves constructed under these conditions were estimated and tests of the hypothesis of equality of the regression lines were performed. The results presented in Tables 1 and 2 show that the initial dose of follicle-stimulating hormone did not modify the corpus hæmorrhagicum response to luteinizing hormone administration. When 20 or 40 I.U. of pregnant mare serum were used, the slopes of the two regression lines were not different ($t = 0.19$). The results presented in Table 3 show that variations in follicle-stimulating hormone/luteinizing hormone ratio of the test material had no influence on the number of corpora hæmorrhagica formed by luteinizing hormone. It appears also that ox serum did not affect the ovarian response to luteinizing hormone. The passage of the ovaries through susa, alcoholic iodine, alcohol, methyl benzoate and finally benzene renders them transparent and corpora hæmorrhagica could be easily counted.

Thanks are due to Mr. Abd-El-Wahab S. Ahmed, of the United States Naval Medical Research Unit No. 3, Cairo, Egypt, for supplying us with the animals used in this investigation.

Carbon Dioxide Assimilation by *Leishmania donovani*

WHILE studying the glucose metabolism of *Leishmania donovani*, the protozoan organism causing visceral leishmaniasis, it has been found that cell suspensions of this organism in a saline-bicarbonate buffer containing glucose can assimilate a measurable amount of carbon dioxide along with the formation of different acidic end products[1].

L. donovani, strain 81, cultured on Ray's medium[2] at 22–24° C. and recycled every three weeks from the Nicolle-Novy-McNeal medium, was used in this study. After growth for three days on Ray's medium, the organism was scraped from the surface of the agar, washed twice with ice-cold isotonic saline by centrifugation at 3,000 r.p.m. for 10 min. and finally resuspended in isotonic saline.

Standard conditions used for the measurement of carbon dioxide assimilation were as follows: 3·0 ml. of the complete reaction mixture contained 15 μ moles of sodium bicarbonate (*p*H 7·3), 30 μ moles of glucose, 1 ml. of cell suspensions in isotonic saline containing 1·5–2 mgm. protein nitrogen. Incubations were carried out for one hour in conventional Warburg manometric vessels at 37·2° C. in an atmosphere 95 per cent nitrogen and 5 per cent carbon dioxide.

Results from three typical experiments showing the carbon dioxide balances during anaerobic glucose breakdown by cell suspensions of *L. donovani* are presented in Table 1. It will be seen that the amount of carbon dioxide assimilated by the organisms under these conditions varies from 32 μl. to 80 μl. The variation in the amount of carbon dioxide fixation was afterwards found to be due to the different growth stages of the culture used. Table 2 represents figures for the stoichiometric relationship between glucose utilized, acid produced and carbon dioxide fixed in three typical experiments carried out under standard experimental conditions. It will be seen that nearly 0·30–0·36 mole of carbon dioxide is incorporated per mole of glucose consumed. Results using growing culture indicate that the amount of carbon dioxide fixed varies with the age of culture; with two days old growing culture the molar ratio of carbon dioxide fixed per mole of glucose utilized is nearly one. From Table 2 it will also be seen that an average of 1·5 moles of acids are formed per mole of glucose metabolized. Chemical analysis of the different acids that are formed indicated that the major products were non-volatile in nature, and among them succinic acid predominated although malic acid formation has also been noted.

Table 1. CARBON DIOXIDE BALANCES DURING ANAEROBIC BREAKDOWN OF GLUCOSE BY *L. donovani* SUSPENSIONS

No of Exp.	* Total available carbon dioxide (μlitre)	Carbon dioxide liberated due to acid formation	Residual carbon dioxide	Carbon dioxide fixed
	a	*b*	*c*	*a*–(*b* + *c*)
1	262	144	74	44
2	267	150	37	80
3	126	82	12	32

Table 2. CARBON DIOXIDE ASSIMILATION BY *L. donovani* SUSPENSIONS

Expt. No	Glucose consumed (μmole)	Total acid formed (μmole)	Carbon dioxide fixed (μmole)	Carbon dioxide fixed/ Glucose used
1	3·1	4·4	1·1	0·36
2	6·1	8·6	1·9	0·31
3	5 3	7 8	1·6	0 30

When glucose was replaced by glycerol, ribose or pyruvate, no measurable amount of carbon dioxide fixation was noticed. Of the various inhibitors tried, DNP (10^{-4} *M*), α-α′-dipyridyl (10^{-3} *M*) and 8-hydroxyquinoline (10^{-3} *M*) were found to have marked inhibitory effects on the glucose utilization as well as on the carbon dioxide assimilation. It seems that the carbon dioxide assimilation by this protozoal organism is in some way related to the glucose metabolism. The high rate of carbon dioxide assimilation may also be complementary to the very active transaminase system reported to be present in this organism[3].

Detailed studies on the biochemical basis for the carbon dioxide requirement of this protozoal organism are in progress and will be reported elsewhere.

HÆMATOLOGY

Hæmolytic Properties of Immune Chicken Antibody

IN the course of a study of immunological responsiveness of chickens to foreign red blood cells our interest was attracted by the observed discrepancy between high agglutination titres of immune chicken sera and their inability to show lytic properties in the presence of complement. It is well known that different antibody–antigen systems exhibit different abilities to fix guinea pig complement when mammals are used as antibody producers[1]. The failure of immune bird sera to show a significant complement-fixing activity was mentioned by Meyer[2] and by Rice[3] in birds infected with ornithosis virus and *S. pullorum*. It was postulated that avian antibody formed with antigen non-complement-fixing aggregates[4], and that avian antibody lacked some character that was important for combining with complement[5]. This problem, however, was not further explored, and all available data were based on the experiments made with guinea pig complement. It seemed, therefore, reasonable to investigate in a preliminary way whether or not chicken antibody hæmolyses red cells in the presence of complement from different animal species.

Hæmolytic sera were prepared by inoculating intravenously Rhode Island Red pullets with 5 per cent suspension of duck and rabbit erythrocytes (two series of three injections each, followed by re-injection after 20 days). The diluent for all reagents was sodium chloride–veronal buffer *p*H 7·3–7·4 containing

* In all cases the complement units were present in the supernatants after incubation.

optimal concentrations of calcium and magnesium ions[6]. Sheep, duck and rabbit red cells (3 per cent suspension; *O.D.* 0·453; Beckman spectrophotometer at 541 mμ) were standardized as in Osler *et al.*[7] Pools of fresh sera from different animal species served as the source of complement. The sera were stored at – 65° C. The hæmolytic complement activity of pools was titrated with sheep red cells sensitized with rabbit hæmolysin, and the titre estimated in 50 per cent hæmolytic units. Two and five 50 per cent complement units were used in titration of chicken antisera. The dilutions of antisera were in the range of 1 : 2 to 1 : 3,000. Duck and rabbit erythrocytes were sensitized in chicken anti-duck and anti-rabbit sera, respectively, for 30–90 min. The incubation with two or five complement units lasted 60–90 min. All reactions were carried out at 37° C. Complement hæmolytic units left in supernatants were estimated with sensitized sheep erythrocytes (rabbit hæmolysin). The chicken immune sera were also examined for the presence of agglutinins, and pools of animal sera were investigated for the presence of normal hæmolysins for duck and rabbit erythrocytes.

Agglutination titres of immune chicken sera were 1 : 1,000–1 : 4,000 for rabbit, and 1 : 120–1 : 1,000 for duck red cells. Some animal sera were very poor in complement (ground-squirrel, horse, sheep, ox and owl). It is evident that complement of different animal species was involved in the hæmolysis of sensitized sheep erythrocytes. On the other hand, no hæmolytic activity of chicken anti-duck and anti-rabbit sera could be observed in the presence of complement. It is interesting to note that normal hæmolysins in avian and animal sera exhibit hæmolysis. This observation may suggest that some differences exist between normal hæmolysins and immune hæmolysins in avian sera.

It is difficult to believe that avian species are not able to produce immune hæmolysins. The failure of immune chicken antibody to hæmolyse red blood cells is probably due to its peculiar behaviour in fixing complement. It should, however, be borne in mind that the complement-fixation is a multiple step reaction of very complex nature which may be affected by a variety of conditions, and in which the complement components react disproportionately[8]. Our knowledge about complement reaction is based mainly on the data obtained from the experiments with guinea pig complement and sensitized sheep erythrocytes. But one is confronted with a somewhat different situation when working with avian antibody. The present experiments suggest that immune hæmolysis in which avian antibody is involved differs to some extent from other immune hæmolyses and requires further study which will probably reveal important information about the mechanism of the action of complement.

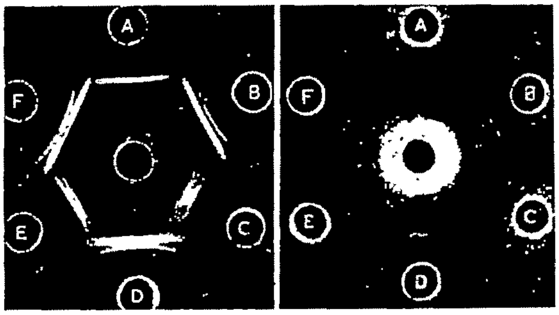
Individual Specific Nature of the Cold Auto-Antibodies of Acquired Hæmolytic Anæmia

DURING the course of an immuno-chemical study of the cold agglutinins present in the sera of patients suffering from acquired hæmolytic anæmia of the cold-antibody type, evidence was obtained which indicated that they were immunologically distinct.

Sera from seven patients were available. Antisera were prepared in rabbits, (1) against the cold antibodies of two of these patients, eluted from erythrocyte stroma, (2) against separated cryoglobulin (acting as a cold antibody) derived from one patient, (3) against γ_1-globulin separated by starch-block electrophoresis from the serum of a patient with acquired hæmolytic anæmia secondary to lymphosarcoma, and (4) against γ_1-globulin separated from a normal serum. The antisera were tested for their reactions by double diffusion in agar gel and immuno-electrophoretic techniques[1].

When the rabbit antisera produced against the pathological cold agglutinins were absorbed with 2·5 mgm. per ml. of γ-globulin (Lister Institute, London) and tested by double diffusion in agar gel against the homologous and heterologous cold-antibody-containing sera and a normal serum, the normal serum produced a single line of precipitate whereas each of the pathological sera produced two lines of precipitate (Fig. 1*a*). The lines formed by the homologous serum showed a reaction of partial identity (cross-reaction) with those formed by the heterologous sera or normal serum, as indicated by spur formation. This suggested the presence of individually specific groupings in the homologous cold-agglutinin protein.



a *b*

Fig. 1. *a*, Photograph of an agar-gel-diffusion plate showing the precipitation pattern of a human serum containing high-titre cold agglutinin (cups *B*, *D* and *F*) and two other human sera also containing high-titre cold agglutinins (cups *C* and *E*) and a normal human serum (cup *A*) The central cup contains rabbit antiserum against the cold agglutinin of the serum used in cups *B*, *D* and *F* and was absorbed with a minimal amount of γ-globulin. The human sera were diluted 1 in 4. *b* Photograph of an agar-gel-diffusion plate showing the precipitation pattern of a human serum containing high-titre cold agglutinin (cups *B*, *D* and *F*) and two other human sera also containing high-titre cold agglutinins (cups *C* and *E*) and a normal human serum (cup *A*). The central cup contains rabbit antiserum against the cold agglutinin of the serum used in cups *B*, *D* and *F* and was absorbed with twice its volume of normal serum (central cup). The human sera were diluted 1 in 4

When the antisera were further absorbed with an excess of pooled normal human serum or with the γ_2- and γ_1-globulin fractions separated electrophoretically from normal human serum, they reacted with homologous serum only (Fig. 1*b*). No reaction was discernible with the heterologous pathological sera or normal human serum even when the gel-diffusion plates had been kept at 37° C. for 3 months. Exactly similar reactions were obtained when the cold agglutinins eluted from erythrocyte stroma were used as test antigens in place of the pathological sera.

Further experiments showed that the formation of precipitin lines by the homologous serum only could not be explained by non-specific precipitation due to the presence of heat-labile components of complement, by incomplete absorption of the antisera or by the presence of different globulin groups[2] in the serum used for absorption and the patient's serum. It is of interest to note that when the rabbit antiserum produced against a normal γ_1-globulin was similarly absorbed, it failed to react with any normal or pathological serum, indicating complete neutralization of the antibodies contained in it.

Although specific globulins have been identified by their Gm groups[2] and specific differences reported between the macroglobulins of Waldenstrom's macroglobulinæmia[3], globulins with antibody properties are not usually considered as having individually specific characteristics. The immunological differences observed may have a counterpart in the subtle differences in serological properties already observed by Dacie and de Gruchy[4] in the antibodies of acquired hæmolytic anæmia. The presence of antigenic groupings specific to the cold antibodies of each individual is in accord with the hypothesis that the formation of cold antibodies represents the synthesis of abnormal proteins rather than an immune response on the part of normal antibody-forming tissues. The observation could perhaps be taken to favour the concept of somatic mutation occurring in the antibody-forming tissues of the patient.

I am indebted to Dr. J. H. Humphrey, of the National Institute for Medical Research, Mill Hill, London, for advice and helpful criticisms and for the supply of γ-globulin preparations used in this investigation.

Distribution of Gm^a and Gm-like among Javanese, Djuka Negroes, and Oyana and Carib Indians

Grubb and Laurell[1] and others have demonstrated that some human sera contain a genetically determined factor capable of inhibiting the ability of serum from selected rheumatoid arthritic patients (RA serum) to agglutinate Rh(+) cells coated with selected incomplete anti-D sera. They called this factor Gm^a and showed that its presence is due to a dominant gene. Thus far various investigators have tested 2,635 Europeans and found that 56·96 per cent were Gm(a+)[2]. Grubb and Laurell[1] found 95 per cent of 74 Eskimos to be Gm(a+), and Steinberg and Giles[3] found 98 per cent of 98 American Negroes to be Gm(a+).

Steinberg and Giles[3] found an RA–anti-D system which tested for a factor which is not Gm^a, Gm^x[3], or Gm^b (ref. 4 and Harboe, M., personal communication). Because its genetic relation to these factors is unknown, the new factor is tentatively called Gm-like. This factor was present in 27·5 per cent of 403 American Negroes and absent in all of 250 Whites. Its presence is determined by a dominant allele.

We have now tested serum from 20 Javanese, 35 Djuka Negroes, 15 Oyana Indians, and 19 Carib Indians for Gm^a and Gm-like. The method of testing was that described by Grubb and Laurell[1]. The samples were collected by Dr. Vincent Butler in Surinam (Netherlands Guiana). The Djuka Negroes are descendants of slaves who escaped into the jungle shortly after importation into Dutch Guiana. The Oyana Indians are an isolate of jungle Indians, living along a river in the interior of Surinam. The Carib Indians are coastal. So far as we know, these people have not intermarried with other ethnic groups.

All 89 samples were positive for Gm^a. The tests for Gm-like were done blind in the sense that all sera were numbered with no indication of the ethnic origin of their donors. The results of the tests for Gm-like are presented in Table 1.

The samples are small; hence, it cannot be established that the difference in frequency of Gm-like(+) among Javanese and Djuka Negroes is significant ($P > 0{\cdot}3$), if indeed the difference is

Table 1. Results of Tests for Gm-like on Sera from Javanese, Djuka Negroes, Oyana Indians and Carib Indians

		Gm-like			
		+		–	
	Total	No.	Percentage	No.	Percentage
Javanese	20	10	50	10	50
Djuka Negroes	35	22	63	13	37
Oyana Indians	15	0	—	15	100
Carib Indians	19	0	—	19	100

significant. There is little doubt, however, that the frequency of Gm-like(+) among the Indians is less than that among the other two groups [P (Javanese–Oyana) $\sim 0\cdot002$, P (Djuka Negroes–Oyana) $< 0\cdot0001$]. Similarly, there is little doubt that the frequency of Gm-like(+) among the Indians is less than that among American Negroes [$\chi^2_{(1)}$ (corrected) $= 4\cdot33$, $P < 0\cdot05$ for Oyana *versus* American Negroes] or that the frequency of Gm-like(+) among the Djuka Negroes is greater than that among the American Negro ($\chi^2_1 = 19\cdot79$, $P < 0\ 001$).

The data are too few to permit a discussion of the ethnic and racial distribution of these genes (*Gm^a^* and *Gm-like*) beyond stating that the frequency of *Gm*^{a} among the coloured peoples seems to be 100 per cent and that *Gm-like* is essentially absent in Whites and possibly in South American Indians and occurs among Javanese and Negroes. Further data are required. The wide variation in frequency of *Gm-like* among various ethnic groups indicates that it may be a useful tool for anthropologists and others interested in population problems.

We are deeply indebted to Dr. Butler for making these sera available to us and to the hospital and laboratory of the Aluminium Co. of America for making their facilities in Surinam available for the collection of the blood specimens used in this study.

This investigation was supported in part by a Public Health Service research grant *A*–1931 from the National Institute of Arthritis and Metabolic Diseases, Public Health Service.

Absence of the Diego Blood-Group Antigen in the Lapps

BLOOD-GROUP studies in the Lapps have revealed rather unusual distributions within several blood-group systems[1,2]. The Lapps seemed to have a curious mixture in their blood groups of European features on one hand, and Asiatic ones on the other.

The discovery of the Diego blood-group antigen has given a valuable tool in anthropological investigations[3]. As the Diego antigen is confined to Mongoloid populations, and in view of the possibility of the Lapps being related to these populations, it seemed to be of importance anthropologically to determine whether this factor was present in the Lapps.

We have tested a total of 433 blood samples from Norwegian Lapps for the Diego factor. The anti-Di^a serum and the Di(a+) control cells used in the study were generously placed at our disposal by Dr. Miguel Layrisse, of Caracas, Venezuela. The serum reacted strongly by the indirect Coombs's technique against the Di(a+) cells, whereas all the 433 Lapp blood samples gave negative results.

From Sweden, further results on the blood groups of the Swedish Lapps have just been published[4]. These investigations also include Diego grouping on 220 blood samples, all of them giving negative reactions. Pooling the Swedish and Norwegian data, we find that a total of 653 Lapps have been examined for the Di^a factor. The absence of the factor in a sample of this size seems to exclude any close relationship to the Mongoloid populations carrying this antigen. In this connexion we should, however, like to point out that the Diego antigen was also absent in a population which is usually regarded as Mongoloid, namely, Eskimos from the eastern Canadian Arctic[5,6].

The Norwegian Lapp blood samples were also grouped in the A_1A_2BO, MNSs, P, Rh(C,c,C^w,D,E,e,V), Kell, Lewis(Le^a,Le^b), Duffy(Fy^a), Kidd(Jk^a,Jk^b), and Wright blood-group systems. A report of these investigations will be given elsewhere.

The study was supported by a grant (*E*.082–8) from the Norwegian Research Council for Science and the Humanities.

Haptoglobin in Monkeys

WE have examined the haptoglobin types of a series of blood samples from 27 monkeys (23 *Macaca mulatta*, 1 *Macaca irus* and 3 *Cebus nigrivittatus*). The *Macaca mulatta* and *Macaca irus*, indigenous to India and Java, were purchased from the United States (Trefflich's Bird and Animal Co. Inc.). Since the rhesus monkey species infrequently reproduces itself in captivity, it can be assumed, even though no genetical results were obtained, that these monkeys are probably unrelated. The few *Cebus* samples examined came from the Higuerote (Miranda State) and Tamanaco (Guárico State) regions, in Venezuela.

The method used for the study of haptoglobins and their differentiation is based mainly on the methods of Smithies[1] and Allison and ap Rees[2] and has already been outlined[3]. Thanks to these methods there exists no doubt as to the classification of haptoglobins.

All the monkeys examined, both from Venezuela and from India and Java, were found to have type 1–1 haptoglobin, probable genotype $H_p{}^1/H_p{}^1$.

The number of monkeys used in our studies is relatively small for definite conclusions to be reached. Should future investigation confirm that monkeys have only one type of haptoglobin, then this finding could be phylogenetically significant, since both monkeys and man belong to the same primate order. In all probability there only existed in the past what is now called type 1–1 haptoglobin, from which the other types known at present are derived by mutation. It would be interesting to know, in this connexion, whether any human populations exist the haptoglobin of which belongs to type 1–1 only. If not, one would be inclined to think that this change probably occurred during or after the evolution of the *Homo sapiens* from non-human and early human types. It is not yet known whether such a mutation has or has not actually favoured this evolution.

Several authors[4-6] have dealt with the much discussed problem of whether the polymorphism of present man is either a recent acquisition or has been directly inherited from his non-human ancestors. Studies made on several species of monkeys in relation to their blood groups as well as to their ability to taste phenylthiocarbamide[4,7] have revealed that the genetical polymorphism of man, in this connexion, is a property common to all primates. If our findings are confirmed, we may be facing a gene (H_p) specifically showing a difference between man and other primates.

We wish to thank Dr. Otto Núñez-Montiel and Dr. Frieda Herold, of the Virus Laboratory of this Institute, for the collection of the blood specimens, and Mr. Alfredo Pansini, of the translation and publication department, for the translation of the Spanish text.

A Survey of Abnormal Hæmoglobins in Portuguese Guinea

IN 1957–58 we conducted a survey of abnormal hæmaglobins among the indigenous population of Portuguese Guinea, during which 9,224 blood samples were collected.

In each case, erythrocytes were tested for sickling, and their hæmoglobin was examined by paper electrophoresis of pH 8·6. When fast-moving hæmoglobins were detected these were submitted also to paper electrophoresis at pH 6·5 and compared with standard samples of known hæmoglobin variants. In the case of hæmoglobin *N*, the first sample we collected was kindly classified by Dr. H. Lehmann in London; after this, further instances of hæmoglobin *N* were classified by ourselves by comparison with this first sample. For identification of hæmoglobin *K*, a sample of *K* obtained during a previous survey at St. Thomas and Prince Island, and one of hæmoglobin *J* supplied by Dr. Lehmann were used. The results of the survey are given in Table 1.

The abnormal hæmoblogins found were *S*, *C*, *K* and *N*.

Not infrequently we found a blood to give a positive sickling test, but not to show the presence of hæmoglobin *S* on electrophoresis. In every case, blood was again withdrawn and submitted to the same tests. In every case, hæmoglobin *S* proved once more to be absent on paper electrophoresis, and the sickling test was negative on the second occasion. We consider that sickling-rates among populations based solely on the sickling test are subject to error, due to false sickling.

The frequency of hæmoglobin *S* varies greatly among the different tribes. As a rule we can say that it is much more common among the Moslem tribes than among the Fetichists.

Hæmoglobin *C* was seen only among the Moslem tribes, which are those with closer relationships with the neighbouring countries.

Hæmoglobin *K* was first described by Cabannes and Buhr[1] among the Algerian Kabyles. Later, Robinson *et al.*[2] found it twice in Liberia, calling it hæmoglobin Liberian II. It has been further found by Ager and Lehmann[3] in an East Indian family, and by Edington and Lehmann among 3 Dagombas of the Northern Ghana, by Cabannes and Sansarricq[1] among 2 Senefous of the High Volta, by Cabannes and Gavanou[1] in one Touareg from the Hoggar, and by Trincão *et al.*[4] in 2 individuals from St. Thomas Island. In Portuguese Guinea we found 8 instances of this rare hæmoglobin; 6 among the Moslem tribes, and 2 among the Fetichists.

* Tribes living in neighbouring territories and encountered by chance in Portuguese Guinea.
† Moslem tribes.

Hæmoglobin *N* seems to be very rare. It was first seen in 8 members of the Mande tribe of Central Liberia by Robinson *et al.*[2], who called it Liberian I. Ager and Lehmann mention two further instances, one from Ghana and one from Nigeria. Further instances have been reported from Portuguese Guinea. It seems interesting to point out that recent surveys of abnormal hæmoglobins among some 2,000 Nigerians failed to reveal any further example of this rare hæmoglobin variant (personal communication, Dr. H. Lehmann).

PATHOLOGY

Chorioallantoic Membrane Lesions produced by Inoculation of Adult Fowl Leucocytes

INTEREST in the reaction of the chick embryo to inoculation with adult homologous tissues, noted in 1916 by Murphy[1], has been renewed by the investigations of Simonsen[2] and Cock and Simonsen[3], which indicate that the alterations in the embryo, including splenomegaly, hepatomegaly, and hæmolytic anæmia, result from an immunological attack by the adult cells on the embryonic tissues. This communication reports that cell suspensions prepared from adult fowl blood, spleen or thymus, when placed on the chorioallantoic membrane, produce characteristic membrane lesions in addition to splenomegaly and hepatomegaly. The chorioallantoic lesions closely resemble the splenic nodules observed by Isacson[4] which developed in 11–15 day chick embryos following intravenous injection of adult homologous leucocytes or spleen cells. Isacson suggested that the splenic nodules represented foci of adult donor cells which were stimulated to proliferate by contact with foreign embryonic antigens, and which were afterwards walled off and destroyed by the maturing embryo.

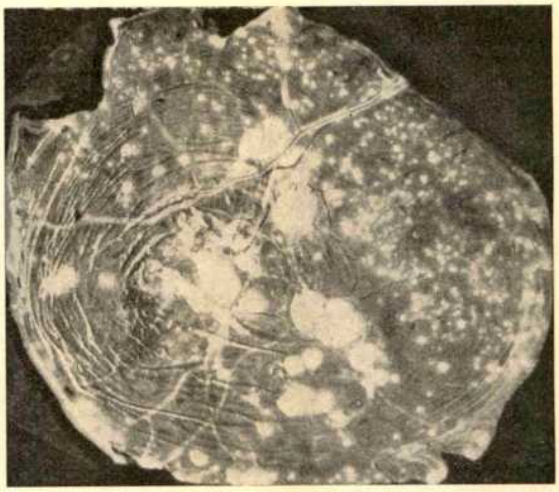

Fig. 1. Chorioallantoic membrane from a chick embryo inoculated at 12 days with a suspension of adult fowl leucocytes and harvested after 6 days incubation at 38° C. Typical large nodules are shown with many small foci which may be of secondary origin.

The chorioallantoic lesions produced by inoculation of adult homologous cell suspensions on to the membrane of 10–14 day old embryos required 4–5 days to develop to the stage illustrated in Fig. 1. At this mature stage they appeared as raised yellow or white nodules, 2–4 mm. in diameter, showing a semi-translucent peripheral zone, and a firm, opaque central core which could be readily shelled out from the surrounding tissue. Multiple tiny opaque areas were sometimes present as well, but they were a less constant feature. Microscopically the inoculated membranes showed a complex variety of changes; only those which appear to be concerned directly with the characteristic nodular lesions will be considered here. The sequence of development of the nodular lesions was similar to that of the splenic nodules described by Isacson[4]. Within 48 hr. after inoculation with adult cells, rounded collections of multiplying mononuclear or spindle-shaped cells were observed in the mesodermal layer of the membrane. By three days, many fibroblasts, mononuclear cells and granulocytes were found surrounding the cell foci. Somewhat later the foci were invaded by granulocytes and underwent necrosis. Infiltration of the adjacent membrane tissue with granulocytes was a frequent and striking feature in the late stages. The alterations in the chick embryo were similar to those which occurred subsequent to intravenous injection of adult homologous blood and spleen cells[2,4]. Any given cell concentration, however, evoked more marked changes in the embryo when given intravenously than when inoculated on to the chorioallantoic membrane. Following either route of inoculation, characteristic nodules developed in the spleen and less frequently in other sites, including the thymus, proventriculus, bone, muscle and subcutaneous tissue. Widespread granulopoiesis occurred, particularly in the periportal areas of the enlarged liver.

The production of the chorioallantoic and associated embryonic lesions by adult fowl cells was a highly reproducible phenomenon. The blood of all the eight adult fowl donors tested, including four in-bred White Leghorn, one New Hampshire Red and three White Leghorn-Australorp hybrid fowls, was effective. As with other manifestations of the donor versus host reaction in avian embryos[2,5], the leucocyte fraction of the blood was found to be responsible for this phenomenon; red blood cells and serum were incapable of producing characteristic nodular membrane lesions. It was also observed that the ability of the leucocytes to induce the lesions was abolished by freezing and thawing, and that white blood cells and spleen cell suspensions from embryonic donors were ineffective. Adult fowl spleen and thymus cell suspensions were capable of inducing characteristic chorioallantoic lesions, although thymic cells appeared less effective than spleen cells and leucocytes.

The number of nodular chorioallantoic lesions which developed depended upon the number of cells inoculated on to the membrane. An inoculum containing 10^4–10^5 peripheral blood leucocytes was required to produce a single nodule. When graded concentrations of cell inocula were given, an approximately proportional relationship was observed between the number of cells introduced and the number of nodular lesions produced. Several experiments have been performed with highly in-bred strains of White Leghorn fowls and embryos. Embryos of the in-bred line responded with approximately the same number of membrane lesions as hybrid White Leghorn-Australorp embryos when inoculated with leucocytes from an unrelated donor fowl. However, when cells from an in-bred donor were placed on the chorioallantoic membranes of isologous embryos, the number of lesions which occurred was far less than the number produced by the same cell suspension on unrelated hybrid embryos.

The investigations made to date indicate that the nodular chorioallantoic membrane lesions result from an immunological reaction between the adult cells and embryonic recipient, presumably of the 'donor versus host' type. The data suggest that the production of lesions requires a significant antigenic disparity between donor and host. In regard to the number of nodules produced, it is a reasonable assumption that each lesion arises as a result of the effective implantation of a single donor cell, but further work will be needed to establish what factors are responsible for the ratio of 10^4–10^5 : 1 between cells inoculated and nodules observed. It may be that a large fraction of the leucocytes are potentially capable of nodule formation but that essentially accidental factors allow only a minute proportion actually to initiate production. At the other extreme, it may be that a very small proportion of cells predetermined to react with the effective isoantigens are responsible for the lesions.

Irrespective of the way the nodules are initiated, it seems legitimate to regard them as arising by proliferation of immunologically competent donor cells in response to antigenic stimulation by components of the embryo. If this view is correct, the phenomenon of chorioallantoic nodule formation should provide a useful approach to certain of the problems of current immunological theory, and may be particularly relevant to the clonal selection hypothesis of Burnet[6].

I wish to express my sincere gratitude to Sir Macfarlane Burnet for his stimulating interest and advice in this work.

Influenza A′ Infection of Cultured Cells of Whole Mouse Embryos

CELLS of whole mouse embryo grown in culture have been used for work with polyoma virus[1,2], and influenza viruses have been grown in cultures of other mammalian tissues such as monkey kidney[3,4], human embryo kidney and lung[5] and bovine embryo kidney[6].

For a recent study of the 'eclipse' phase in the multiplication of influenza *A′* virus, the virus was grown in cells of mouse embryo lung[7]. A greater quantity of tissue can be obtained for culture more easily by using whole mouse embryos, and as is described below, such cultures support the growth of this virus.

Whole mouse embryos taken from stock albino mothers bought from a dealer were weighed, chopped up and treated with trypsin. The cells so released were suspended in a medium consisting of inactivated normal rabbit serum, 1 part, 2·5 per cent lactalbumin hydrolysate, 1 part, and Hanks's balanced salt solution, 8 parts, together with sufficient penicillin, streptomycin and mycostatin to control possible contaminants. Such a cell suspension, containing 5–10 × 10^5 cells per ml., was put into insulin vials in 2 ml. lots and produced monolayer cultures suitable for infection with virus after incubation for 18 hr. at 36·5° C.

Infection was achieved by removing the medium from the cells and, after washing them with balanced salt solution, replacing it with the same volume of a 1 : 50 dilution in 5 per cent normal rabbit serum in balanced salt solution of homogenized mouse lung suspension, representing a later passage of the strain of influenza *A′* used in the earlier work[7]. The cells were held at 36·5° C. for 45 min.; then the infecting suspension was removed and kept for infectivity titration in hens' eggs. The cells were washed in 3 changes of balanced salt solution and their original medium restored. This medium was sampled for infectivity titration 2 hr. and 24 hr. after the first contact of the cells with the infecting suspension.

Table 1. GROWTH OF INFLUENZA *A′* VIRUS IN CULTURED CELLS OF WHOLE MOUSE EMBRYOS, SHOWING EMBRYO WEIGHTS

Experiment	Embryos, Mean wt. (gm.)	50 per cent Egg Infective Dose (ml.)		
		Infecting suspension	Culture medium 2 hr.	Culture medium 24 hr.
1	0·08	$10^{-6.2}$	$10^{-1.7}$	$10^{-3.5}$
2	0·11	$10^{-4.7}$	$10^{-2.5}$	$10^{-3.0}$
3	0·31	$10^{-4.6}$	$10^{-2.3}$	$10^{-4.6}$
4	not recorded	$10^{-4.8}$	$10^{-2.8}$	$10^{-5.6}$

As can be seen from Table 1 the system supported multiplication of the virus, the increase in infectivity for eggs in 22 hr. ranging from 0·5 to 2·8 $\log_{10}$ units. This increase may be compared with the finding that medium removed from infected cells at 2 hr., when its mean 50 per cent egg infective dose in three further experiments was $10^{-3.1}$ ml., was rendered completely non-infective by 22 hr. incubation at 36·5° C. in the absence of cells.

Action of Antibodies and Plasmin on Ehrlich Ascites Tumour Cells

THE mechanism of cell destruction in allergic inflammation is not well understood. Two explanations for production of cell damage have, however, been proposed: (*a*) that the antigen-antibody reaction causes, in some non-specific manner, permeability changes in cells which result in the release of active mediators of inflammation (histamine, etc.) and that the latter are directly involved in the allergic process[1]; (*b*) that the antigen-antibody reaction activates proteolytic enzymes (plasmin, proteases) that injure the cells[2-4].

The second hypothesis has been supported by some experimental evidence; but the exact mechanism of cell destruction by proteolytic enzymes remains to be elucidated. Studies on the effect of cytotoxic antibodies against Ehrlich ascites tumour cells have revealed that the cytopathogenic changes induced in tumour cells by the action of specific antibodies were very similar to those obtained by the action of streptococcal hæmolysins[5]. It was also found that tumour cells treated with streptococcal hæmolysins were completely disintegrated by the presence of small amounts of proteolytic enzymes[5]. Therefore the action of plasmin was tried on tumour cells affected by specific antibodies, so as to obtain some insight into the role of blood proteolytic enzymes in this process. Rabbits were immunized with homogenates of Ehrlich tumour cells according to the method of Salk and Laurent[6]. Four weeks following the first injection, the sera of these rabbits up to a titre of 1 : 20 caused a distinct cytopathogenic effect on tumour cells. The action of antiserum was found to be dependent on complement.

In a typical experiment 0·1 ml. of washed ascites cells (10^8/ml.) were incubated at 37° C. with 0·1 ml. of immune serum and with 0·8 ml. of $M/15$ phosphate saline buffer *p*H 7·4. Five minutes following addition of antiserum, agglutination of the tumour cells occurred; while 10 min. later first signs of cellular damage could already be seen. The cells appeared swollen, the nucleus became visible and was surrounded by a clear cytoplasmic space with granules close to the nucleus. Thirty minutes following the addition of antiserum, the majority of the tumour cells appeared dead, as established by staining with trypan blue. Sixty minutes following the addition of antiserum the total number of the tumour cells was reduced by 25 per cent (Table 1). The remaining cells, though swollen, retained their cytoplasmic membrane, and the nucleus appeared undamaged. Only a very small amount of cell debris could be seen. These results are consistent with the findings of Flax[7] and Goldberg and Green[8], who tested the action of antiserum against Ehrlich and Krebs ascites tumours respectively. The action of human and rabbit plasmin, activated by streptokinase SK–100 units/ml. (Varidase-Lederle), was tested on tumour cells affected by antiserum. Rabbit and human plasminogen were prepared according to the method of Ratnoff[9]. In addition, antiserum was also used as a source of plasminogen. Plasmin was assayed according to the method described by Remmert and Cohen[10]. Plasmin (1–50 units/ml.) was added to Ehrlich tumour cells which had been pre-incubated for 15 min. at 37° C. with antiserum, and which showed distinct swelling. As soon as 10 min. after addition of plasmin, the swollen cells began to disintegrate, and 5 min. later large accumulations of cell debris mingled with ghosts of swollen cells could be seen (Fig. 1). Incubation with increasing concentrations of plasmin caused a proportional increase in the percentage disintegration of the tumour cells (Table 1). Under the same experimental conditions neither plasmin alone (250 units/ml.) nor plasmin incubated with heat-inactivated antiserum (56° C. for 30 min.) or streptodornase (1,000 units/ml. present in 'Varidase' preparations) had any effect on the morphology or total number of cells (Table 1). The leucocytes which were present in the tumour suspensions incubated with antiserum and plasmin appeared undamaged (Fig. 1). If on the other hand plasmin was added to tumour cells either simultaneously or 5 min. after addition of antiserum (before any apparent damage to cells occurred) only few cells appeared swollen and no disintegration of tumour cells was observed. These results are consistent with the findings of various investigators[11] that plasmin destroys complement. This assumption seems plausible since the action of cytotoxic antibodies against Ehrlich tumour cells have been found to be dependent on complement[7]. Thus, to obtain rapid disintegration of cells by the combined action of antiserum and plasmin the antibody-complement complex must first damage the cell membrane. This leads to altered permeability of the cell membrane which may allow plasmin either to penetrate into the cells or to attack cell wall substrates which have been unmasked by the action of antiserum. This would result in the depolymerization of cell components leading to cell disintegration.

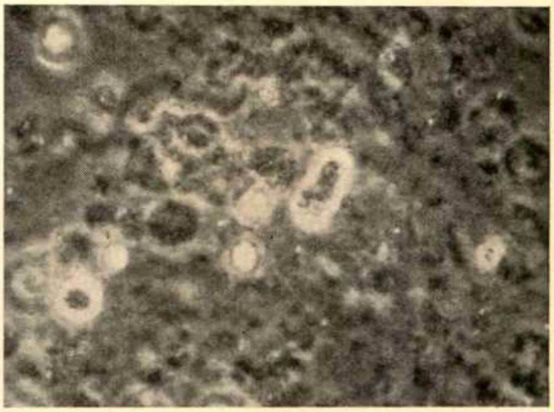

Fig. 1. Ehrlich ascites tumour cells incubated for 15 min. at 37° C. with antiserum and plasmin (50 U./ml.). Plasmin was added to tumour cells after they were in contact for 15 min. with antiserum. Note the massive destruction, accumulation of cell debris, few tumour cell ghosts and several undamaged leucocytes. (× 450)

Table 1. ACTION OF ANTISERUM AND HUMAN PLASMIN ON EHRLICH TUMOUR CELLS

Reaction mixture	Cells remaining* (per cent)
Tumour cells in buffer[a]	100
,, ,, + 10 per cent antiserum[b]	75
,, ,, + 10 per cent inactivated antiserum[c]	100
,, ,, + Plasmin (250 U/ml.)	100
,, ,, + 10 per cent antiserum + plasmin (1 U./ml.)[d]	54
,, ,, + 10 per cent antiserum + plasmin (10 U./ml.)	10

* Average of the counts of 3 experiments after 60 min. incubation at 37° C.

All the cells that still possessed a cell membrane, no matter how damaged they appeared, were counted.

Usually 500 cells were counted in each experiment.

[a] Ehrlich tumour cells 10^7/ml. washed with phosphate-buffer in saline, *p*H 7·4.

[b] Rabbit anti-Ehrlich serum.

[c] Anti-Ehrlich serum heated to 56° C. for 30 min.

[d] Tumour cells were incubated with antiserum for 15 min. at 37° C. before addition of human plasmin. Similar results were obtained with plasmin prepared from rabbit's serum.

The action of plasmin was found to be unspecific as both trypsin and papain were active in this respect. These *in vitro* findings raise the possibility that plasmin or other tissue proteolytic enzymes may be directly involved in cell destruction induced by the antigen-antibody reaction.

Work is in progress to determine what part, if any, these factors play in cellular damage *in vivo*.

This work was supported in part by a grant from the Rose Protus Social Service Club, Chicago, Illinois.

Dietary Fats and Thrombosis

In order to study the influence of the fat content of food on the occurrence of thrombosis in the arterial and venous system, a group of 133 hospital patients aged 65–90 years were treated with a diet in which butterfat, margarine and lard were replaced by vegetable oils (unhydrogenated corn oil and soybean oil). The daily intake of vegetable oils was about 40 gm., or half the total fats. The time of treatment of the 133 patients ranged from 1 to 17 months (average 4·7 months) representing a total of 52½ years. For comparison, a control group of the same size and composition who received an ordinary hospital diet containing about 80 gm. animal fats (including about 40 gm. butter-fat, margarine and lard) was used. The occurrence of thrombosis and embolism in both groups was diagnosed clinically and post-mortem.

In the treated group only 4 cases of thrombo-embolism were observed: 1 case of myocardial infarction after 6 days of treatment, 1 case of myocardial infarction after 26 days of treatment, both verified by autopsy; 1 case of little stroke with transient aphasia of a few days' duration occurring after 30 days of treatment, and 1 case of pulmonary embolism after 4 months of treatment in a patient with bronchial cancer (verified by autopsy).

In the control group 15 cases of thrombosis were observed: 2 cases of thrombophlebitis (1 case complicated with pulmonary embolism and 1 case with thrombosis in the carotid artery), 2 cases of pulmonary embolism (both verified by autopsy), 5 cases of myocardial infarction (all typical, 2 verified by autopsy), 6 cases of cerebral thrombosis (3 verified by autopsy).

The difference in the occurrence of thrombosis in the two patient groups was statistically significant ($t = 5{\cdot}1$) and cannot be interpreted in terms of variations in age, weight and blood pressure in the groups.

BIOLOGY

Interaction between the Plasma of the Loggerhead Turtle and Toxin of the Portuguese Man-of-War

THE loggerhead turtle, *Caretta caretta*, is reported to eat the Portuguese man-of-war, *Physalia physalis*[1-3]. Where *Physalia* are assembled in windrows, loggerheads are often seen at the surface with eyes closed, eating this siphonophore. *Velella*, an allied species, has also been identified from stomach contents of a turtle which was identified as a loggerhead[4]. *Physalia* is equipped with a singularly potent toxin[5]. This is contained in nematocysts which can penetrate a rubber glove and presumably even the chitinous exoskeleton of a crab's leg. As Barbour pointed out, the dense impenetrable skin of the face and jaws might protect a turtle from some of the obvious hazards of such a feast. However, since tentacles of active colonies have been observed to cling tightly to the skin, gloves, glass containers and even to the polished steel surface of a pair of scissors, it is difficult to explain the ability of the turtle to swallow, much less to digest and survive this meal. We believe that the acid of the stomach contents would inactivate the nematocyst and its contained venom virtually upon contact. The unconcern of the adult turtle with the toxic effects of the nematocysts might be due to the presence of protective antibodies in the blood acquired by contact with *Physalia* early in life. It is the object of this communication to report the results of experiments designed to test this hypothesis.

A 15-kgm. loggerhead turtle which had been in captivity less than one week was obtained from the Miami Seaquarium. The jugular vein was cannulated and the animal was bled. Sufficient potassium oxalate was added to the blood to bring the concentration to 0·2 per cent and the blood was cooled. Later the blood was centrifuged and the separated plasma was frozen at –20° C. without preservative. Toxin of *Physalia* was prepared according to procedures already described[5], with the following modifications: (1) Washed quartz sand and glass-distilled water were used for homogenization of the washed purified nematocysts. (2) After centrifugation, the material was mixed with 4/3 volumes of calcium phosphate gel prepared by the method of Kunitz[6] and was recentrifuged. The water-clear supernatant solution apparently contains all the toxic material. (3) This supernatant solution was lyophilized in tared 5-ml. capsules. These were sealed without admitting air and stored at –20° C. until used.

Fractions prepared in this way have regularly assayed at *LD*90 of 2·5–3·0 mgm./kgm. body-weight of pure strain, 18–25 gm. *C*57 black male mice when the mice are injected intravenously. The lyophilized material dissolves easily and completely. We assume that the entire weight of lyophilized material is toxic for purposes of estimating concentrations. It should be noted that if any significant fraction of the lyophilized 'toxin' were inactive then the active moiety would considerably exceed 2·5 mgm./kgm. in toxicity. The toxin is quite thermolabile and its activity decreases during manipulation.

In one experiment lyophilized toxin was dissolved in glass-distilled water to produce a concentration of 20 mgm./ml. One aliquot was diluted with 19 vol. of 0·9 per cent saline to a final concentration of 1 mgm./ml. (solution *A*, Table 1). The second aliquot was diluted with one volume of turtle plasma

Table 1

Solution	Toxin mgm. (dry weight)	Total diluent added Plasma (ml.)	Water (ml.)	0·9% Saline (ml.)	Final toxin concentration (mgm./ml.)
A	20	0	1	19	1
B	20	1	1	18	1
C	20*	1	1	18	1*
D	20*	1	1	0	10*

* Weight of toxin expected if it were all present in the supernatant solution (*C*) or in the precipitate (*D*).

and then further with 18 vol. of saline to a final toxin concentration of 1 mgm./ml. (solution *B*, Table 1). A precipitate formed when the plasma was combined with the toxin which did not dissolve when more saline was added. This precipitate was uniformly dispersed through the injection fluid and was included in the assay. The third aliquot was combined with an equal volume of turtle plasma and centrifuged to remove the precipitate. The supernatant liquid was assumed to contain all the toxin and was so diluted with saline as to bring the final toxin concentration to 1 mgm./ml. (solution *C*, Table 1). The precipitate was resuspended in a solution consisting of 1 ml. of turtle plasma and 1 ml. of glass-distilled water (solution *D*, Table 1). If all the toxic material were contained in the precipitate the concentration would have been 10 mgm./ml. Table 2 presents the results of assays of these solutions.

Table 2

Solution	No. mice injected	Dose-range (mgm./kgm.)	Surviving after 2 hr.
A	10	2·55–2·61	0
B	10	2·50–2·59	0
C	11	2·57–2·61*	0
D	10	47·0–56·2*	10

* Weight of toxin expected if it were all present in the supernatant solution (*C*) or in the precipitate (*D*)

Apparently all the toxicity originally present in solution *A* is still present in the toxin-plasma combination *B*. The precipitate which was separated and resuspended in saline *D* contained none of the activity. The supernatant solution *C* held all the toxicity of the original combination.

This experiment was repeated twice, with fewer mice, with entirely similar results. These results suggest that the loggerhead turtle lacks blood immune bodies which might be invoked to explain its apparent insensitivity to the toxin of *Physalia*.

Our interpretation does not exclude the possibility that the loggerhead might possess localized tissue antibodies. Phisalix[7] has shown that reptiles, and especially turtles, are less sensitive to the sting of bees than other vertebrates. It is possible that turtles are not susceptible to venoms of the type injected by *Physalia*.

We are grateful to Dr. Wilhelmina Dunning of the University of Miami for providing mice and to the Miami Seaquarium for the loggerhead turtle. These studies were supported by Grant *RG*-5272 from the U.S. Public Health Service, National Institutes of Health.

Elucidation of the Life-cycle of *Fasciola hepatica*

DR. B. DAWES, in his recent communication[1], has made an important contribution to our knowledge of the trematodes. In the interests of historical accuracy and in justice to a great nineteenth-century zoologist I would, however, like to point out that the life-histories of several trematodes, including that of *Fasciola hepatica*, were beautifully and accurately described by J. J. S. Steenstrup in his work "On the Alternation of Generations", translated into English and published as a Ray Society monograph in 1845, nearly forty years before the work of R. Leuckart and A. P. Thomas. Steenstrup solved one of the most difficult of all zoological problems, and his ideas on the alternation of generations were considered so revolutionary that G. Busk, his translator and editor, thought fit to write an apologetic introduction to assuage the anger of his readers.

[1] *Nature*, 184, 1334 (1959).

I AGREE with H. S. Jefferies that historical accuracy is desirable and that the credit for scientific discovery should go where it is deserved. Parasitology owes much to the work of Steenstrup, who demonstrated the 'alternation of generations' which occurs in the lives of some invertebrate animals[1]. This expression was first used in 1819, however, by the Franco-German poet and naturalist, Louis Adelaide de Chamisso, in regard to the life-cycle of the pelagic tunicates known as salps, but the young Danish zoologists showed that it applies to the life-cycles of some cœlenterates, trematodes and other invertebrate animals as well. Valuable discoveries were made also by other zoologists, and some of these were mentioned in Chapter 16 and elsewhere in my book[2], and others have since been indicated by E. G. Reinhard, with special reference to the life-cycle of *Fasciola hepatica*[3].

In using the term 'cercaria', Steenstrup recognized both a discovery and an invention made in 1773 by O. F. Muller. The forms which he called 'nurses' were later named 'rediae' by F. de Filippi in honour of Francesco Redi who, in 1668, made all discoveries in this field possible by destroying the false doctrine of spontaneous generation. Such 'nurses' were first seen in 1818 by Ludwig Bojanus, who called them 'royal-yellow worms' and emergent cercariæ were first seen to encyst in 1807 by C. L. Nitzsch of Halle, who thus witnessed the formation of what Steenstrup later called 'pupae'. Some earlier discoveries made by two of C. A. Rudolphi's pupils did not enter into Steenstrup's considerations, though they concern the trematode life-cycle. In 1831, K. E. Mehlis described the hatching of 'ciliated embryos' from the eggs of trematodes, and in 1837, F. C. H. Creplin observed that such forms (miracidia) emerge from the eggs of *Fasciola hepatica*. Unluckily, Bojanus, Steenstrup and other persons mentioned here by name seem not to have made a study of the parasites of *Limnaea truncatula*, and for this reason did not observe the larval stages of *F. hepatica*. Steenstrup made a brief reference (5 lines) to the adult of this species and then turned to descriptions of echinostome and stylet cercariæ. He did not even mention the larval stages of the liver-fluke, and in fact he did not describe any trematode life-cycle in its entirety. According to Reinhard, the German parasitologist, Davis F. Weinland was the first person to suspect that the larval stages of the liver-fluke occur in *L. truncatula*. In 1875, he "told of finding cercaria-sacs" in the digestive gland of this snail, and he also noted that the cercariæ tended to leave water, which prompted him to suggest that they encysted on herbage and were the young of *Fasciola hepatica*. Thomas was apparently unaware of Weinland's discovery and conjectures, and his well-deserved success was the result of a methodical search for possible snail hosts in localities where sheep were liable to contract liver-rot. The quest was probably simplified by the knowledge that only fishes and molluscs were to be regarded with suspicion because the only animals known to harbour larval trematodes, but success called for all the resources of a most resourceful zoologist.

Differentiation induced as Season Advances in the Embryo-Gametophyte Complex of *Pinus nigra* var. *austriaca*, using Indole Acetic Acid

MAINTENANCE of growth in very young excised gymnosperm embryos in culture medium has been attempted by one of us with limited success. Indefinite growth was never achieved, and at death, differentiation was lacking other than that suggesting initiation of symmetry or polarity.

The present work on *Pinus austriaca* arises out of attempts to find qualitative evidence of physiological relationship in the region of the parental-embryonic threshold. Indole acetic acid, because of its acceptance as a growth-controlling agent, was added to the culture medium in the hope that it would stimulate differentiation during post-zygotic *in vitro* life.

Seeds were gathered at intervals during the year. Their testas were removed under aseptic conditions, and the naked gametophytes were placed on a sterile culture medium buffered to pH 6·0, and containing a known concentration of indole acetic acid. Various concentrations of indole acetic acid were sampled in the course of the experiments.

The gametophytes were harvested, some after two, others after four weeks *in vitro*.

Examination followed sectioning and staining in borax carmine and fast green.

Comparison of several gametophytes grown on an indole acetic acid medium in July immediately following fertilization showed in each case the presence of a meristematic layer crossing the gametophytic tissue. Position of the meristem varied from one example to another. It consisted of contiguous thin-walled cells resembling the fusiform initials of a vascular cambium.

Cells between the periphery of the gametophyte and the meristematic layer had undergone enlargement which produced local swelling. These cells contained little cytoplasm and only a few granules. Cells on the other side of the layer were much smaller, irregularly shaped, and contained a strikingly large number of granules which differed markedly in form from those normally present at corresponding positions in controls.

In many of these gametophytes, the parenchyma cells surrounding the archegonial jackets developed secondary thickenings on all their walls. Thus in these cells pits appeared on all the walls; they were large and circular.

Experiments performed in August, long after fertilization, showed neither the development of meristematic layers in gametophytic tissue nor the development of thickenings and pitting outside the archegonial jackets. Therefore, none of the phenomena arising in July examples occurred in the August ones.

In the older examples a different feature arose not seen in the July ones. At several scattered locations, cells one to three times the volume of neighbouring ones arose. These were thick-walled, lignified, pitted and often anisotropic in polarized light. Cytoplasm and nuclei were not visible in them.

Proembryo ontogeny for indole acetic acid *in vitro* cases differed from that for the controls in both the July and August examples. One cultured proembryo developed reticulate pitting in the walls of the suspensor cells. Others showed inhibited growth. Generally, on the basis that incidence of anomaly and differentiation was less frequent for embryo than for gametophytic tissue, the effect of the indole acetic acid *in vitro* conditions was judged to be less marked for the embryo system.

Experiments performed at the end of March with material collected at that time (nine months after fertilization) showed none of the previously described phenomena.

It may be concluded that: (1) In *Pinus austriaca*, as one example of an embryophyte, parental-embryonic environment shows a differential response to a factor stimulating differentiation. This differential suggests presence of a pattern of organization in which time and morphological events are significant and related. (2) In parental tissue, visual differentiation may be extensive; for example, meristem and massive activity near archegonia, or confined to single isolated cells, for example, lignified structures. In embryonic tissue the effect is always confined to single cells. (3) Indole acetic acid appears to be influential in initiating the differentiation and in effecting its course.

Collection of Urine and Fæces from the Chicken

IN order to examine some factors which influence the intestinal absorption and urinary excretion of calcium and phosphorus in the chicken, a surgical method for the separation of urine and fæces has been developed which depends upon the successful 'exteriorization' of the distal end of the large intestine. This method, which has been employed principally in adult Rhode Island Red females, is equally suitable for adult capons and cockerels. Females operated on one year ago and fed practical rations have maintained normal behaviour, appetite, laying performance and live weight compared with non-operated controls. They have been employed for the daily collection of urine and fæces in various experiments, to be reported elsewhere, ranging from three to ten weeks duration.

Exteriorization of the distal end of the large intestine at a point on the abdominal wall has been previously reported by others. Rothschild[1] reviewed previous reports of techniques while contributing his own method, but mentioned no criteria of health and production in operated birds. Ariyoshi and Morimoto[2,3] described a technique that was afterwards used for nitrogen balance studies in cockerels over a period of six months and which necessitated the use of a special diet. Theirs is the only report of a long-term metabolic study on separated urine and fæces in the chicken.

The principal criticisms, therefore, of the previously described methods are: (1) they fail to provide such criteria of normality as behaviour, appetite and production; (2) there has been insufficient emphasis on, or attempt to explain, the post-operative complications and how to avoid them; (3) none has mentioned the quality of the fæces, which are invariably scant and fluid if there is any degree of stenosis or intestinal atony; (4) no long-term quantitative observations with laying females have been reported.

In carrying out the operation, general anæsthesia and full aseptic methods are essential. The terminal end of the large intestine as it joins the cloaca is ligated, incised, and exteriorized at a point half-way between the ischium and the abdominal mid-line approximately one and a half inches anterior to the ventral lip of the cloaca on the right side. The cloaca now forms a blind sac (except for the oviducal orifice in the female), and urine, which enters it from the ureters, is periodically expelled since the normal defæcation reflexes are retained. To collect the urine, a wooden frame covered with polythene sheet is placed below the wire floor of the cage. The polythene sheet slopes towards a central hole through which the urine flows into a vessel. The fæces, which are firm in consistency and in short lengths, pass out of the exteriorized bowel continually. To collect the fæces, a 100-ml. polythene beaker is inserted into a rubber cuff with a roll end sutured to the skin around the exteriorized bowel.

The production of a successful preparation depends upon the elimination of several post-operative complications. Any degree of stenosis due to inflammation, fibrosis, contraction of abdominal muscle or fascia and skin overgrowth around the exteriorized bowel must be avoided. Stenosis due to any of these factors always induces fæcal obstruction, constipation and intestinal atony. In order to overcome these complications, a thin-walled glass cannula, with approximately the same diameter, is inserted into the exteriorized bowel immediately after the operation. This cannula, through which fæces pass freely, is held in position by a polythene collar sutured to the skin immediately surrounding the exteriorized bowel. After two weeks, by which time contraction around the exteriorized bowl has terminated, the cannula is removed and fæces continue to pass quite freely. In some birds the skin immediately surrounding the bowel tends to overgrow the bowel orifice, but this difficulty is overcome by judiciously cutting it away. The birds remain clean and require little attention except in the course of experiments, when it is necessary to ensure that the fæces collector is securely attached.

I wish to express my thanks to members of the surgical unit at the Cambridge University School of Veterinary Medicine for their suggestions and criticisms, and I am indebted to the British Oil and Cake Mills, Ltd., for the provision of a research studentship which enabled this work to be carried out.

Infection of Peas by Wilt Disease Fungi

A SERIOUS soil-borne wilt disease of peas has been shown to be caused by *Fusarium oxysporum* f. *pisi* (Linf.) Synder and Hansen, and *Fusarium oxysporum* Fr. emend. Synder and Hansen var. *redolens* (Wollenw.) Gordon[1,2]. Both these fungi attack the vascular system of the plant, and a typical internal symptom of the disease is an orange or brick-red discoloration of the vascular tissue.

During the examination of wilted pea plants which had been grown from seed in naturally infested soil it was noticed that, when the lowermost leaves began to wilt, which is the earliest recognizable stage, no discoloration could be found except in the cotyledonary vascular bundles. Furthermore, in plants which showed the curious 'half-leaf' wilt in which half of each leaf was wilted, only one of the two cotyledonary bundles was orange. Following these observations a series of isolations were made from the steles of plants showing various degrees of wilting. All plants with any sign of foot-rot (*Fusarium solani* f. *pisi*) were discarded, and as this fungus was not isolated from any of the experimental plants it is considered that the results in Table 1 refer to the wilt disease alone.

Table 1. DISTRIBUTION OF THE FUNGUS IN THE PLANTS AT VARIOUS STAGES OF WILTING

Leaves		Stem	Cotyledonary bundles		Hypocotyl	Root
Total	Wilted					
8	0	–	–	–	–	–
8	1	–	+	+	–	–
8	2	–	+	+	+	–
8	4	–	+	+	+	+
8	5	+	+	+	+	+
8	6	+	+	+	+	+
Completely wilted plant		+	+	+	+	+
'Half-leaf' wilt		+	+	–	+	+

An examination of Table 1 reveals that in the earliest recognizable stages of the wilt disease the fungus can be isolated from the cotyledonary bundles only; but as the wilt symptoms progressed so did the distribution of the fungus. Where the early stage of 'half-leaf' wilting was present the fungus was isolated from one cotyledonary bundle only. Consideration of the configuration of the vascular system of the pea plant[3] indicates that from a unilateral infection this 'half-leaf' wilting might be anticipated.

Microscopical examination of the distribution of the fungus within the plant confirms the foregoing observations. In 'half-leaf' wilt the fungus extends much farther up the vessels of the wilted side of the stem than of the non-wilted side, and in the root of an extensively wilted plant only two of the three points of the triarch stele, those corresponding to the cotyledonary bundles, contained the fungus.

It was concluded, therefore, that, in peas grown from seed in naturally infested soil, invasion of the host by the fungus is through the moribund cotyledons. Occasionally, where the root has had to curl around the seed before growing downwards, infection has been observed at the junction of an upper lateral root with the tap root. In plants in the first stages of wilting, infection at other points has been recorded in a very few cases, but it has always been associated with other damage, for example, by eelworms.

Field observations confirm these findings but, on land which has been too frequently cropped with peas, the root disease picture is often complicated owing to the multiplication of other soil-borne pests and diseases.

This investigation is continuing, and a more detailed report will be published later. I am indebted to the Agricultural Research Council for a grant enabling me to do this work, to Sir Joseph Hutchinson for laboratory and glasshouse facilities and to the National Agricultural Advisory Service for their co-operation.

Arm Abnormality in *Octopus*

WHILE working through the cephalopod collections of the University of Miami Marine Laboratory I found a specimen which possessed an abnormal third left arm. The arm was divided into two branches. An unusual feature was the presence of a well-developed web between the two divisions as found uniting the bases of normal arms in this species.

Regeneration in cephalopods has been observed and reported by several workers but they are generally concerned with unipedal growth as a result of damage or autonomy. A. E. Verrill[1] reported on the regeneration of suckers in the giant squid, *Architeuthis harveyi*. Parona[2] described the occurrence of two, thin, short arms in the position of the first left arm of *Octopus vulgaris*; the presence of an extra arm between the second and third right arm in *Eledone aldrovandi*; and the vague mention of a divided arm in a specimen of *Eledone moschata*. Hanko[3] cited the occurrence of a split right fourth arm in a specimen of *Octopus vulgaris*. M. Lange[4] concerned herself with the histological processes and method of regeneration and only cited Hanko's 1913 work without further comment. Robson[5] mentioned the occurrence of regeneration, Lange's work, and autophagy. Sasaki[6] noted and figured a monstrosity of *Octopus vulgaris* in which the right fourth arm gave rise to 25 offshoots, all bearing suckers but with no indication of a web. He stated that he had observed such abnormality in two cases, both *Octopus vulgaris*. S. G. A. Jaeckel[7] reproduced Sasaki's figure.

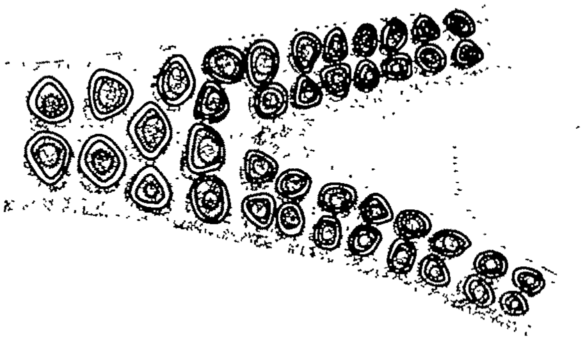

Fig. 1. Ventral view of the split-arm specimen of *Octopus briareus* Robson

The specimen (*Octopus briareus* Robson, 1929, U.M.M.L. 31 : 160) examined by me appears unique in the presence and extent of a web between the two extremities of the split third left arm. An existing web between extra arms has not been recorded previously or at least has escaped notice of the above-cited workers.

The specimen examined was a male, collected by Clench and Dickinson on June 7, 1956, at Big Pine Key, Florida. It was identified by means of the key and description given by Voss[8] for *Octopus briareus*. Basic measurements and indices are given in Table 1. Indices used are as defined by Pickford[9] and Voss[8].

Table 1. MEASUREMENTS (MM.) AND INDICES OF THE SPLIT-ARM SPECIMEN OF *Octopus briareus* U.M.M.L. 31 : 160 (MALE)

Mantle length	51·2
Mantle width	39 5
Mantle width index	77·1
Hectocotylized arm length	173·3
Ligula length	5 6
Ligula index	3·2
Arm order	3.2.4.1

The length of the third left arm (left ventro-lateral arm) as measured from the first basal sucker to the junction of the split is 94·3 mm. When the arm is viewed ventrally (sucker side up) the split sections measure 101·5 mm. and 103·5 mm., left and right side respectively.

The suckers are biserial in the normal fashion from the mouth to immediately below the junction. The second row of suckers, distally from the centre of the junction, is composed of three suckers across. The last row of suckers on the main stem has four suckers across the arm. On each of the divided sections the paired sucker arrangement found on the main stem is present. The web depth is 8·2 mm. between the two branches. A ventral view of the split arm is shown in Fig. 1. Measurements of the split arm are summarized in Table 2.

Table 2. MEASUREMENTS (MM.) OF THE SPLIT THIRD LEFT ARM

Arm length (to base of split)	94·3
Arm length of left branch	101 5
Arm length of right branch	103 5
Depth of web	12 1
Diameter of largest sucker	7·3

This type of growth does not appear to be the result of an arm injury. The web is shallow in this species and the presence of a web (11 per cent of the branched arm length) between the split sections would seem to indicate a mutant or an abnormality caused by injury to the embryo. No adaptive use for this development can be seen as the ligula is well developed and all other arms are intact, nor did the modification appear to be detrimental to the animal as it was in good shape and apparently healthy at the time of capture.

I wish to acknowledge the constructive criticism offered by Dr. G. L. Voss.

Delayed Birth in Marsupial Macropods—the Euro, the Tammar and the Marloo

THE first anecdotal evidence for delayed birth in macropods was given by Carson[1] in 1912. However, the phenomenon of delayed birth in the quokka (*Setonix brachyurus*) and the tammar (*Protemnodon eugenii*) was first investigated in detail by Sharman[2–4].

During a study of the euro (*Macropus robustus*) undertaken by the University of Western Australia we have found many delayed blastocysts lying free in the uteri while the females had 'joeys' in the pouch. The blastocysts were located by flushing out the uteri with physiological saline as described by Sharman[3]. Following this discovery an attempt was made to initiate a delayed birth in an experimental manner. A female euro obtained from the local zoological gardens was found to have a 28-gm. 'joey' in the pouch. This 'joey' was removed and the female isolated from further contact with males. 36 days later examination of this animal revealed a pouch young attached to the teat. Examination on the thirty-fourth day had shown no pouch young.

Previous work by Sharman[4] showed that tammars contain delayed blastocysts, and he has given anecdotal evidence which supported a delayed birth mechanism in this species. We have also produced a delayed birth pouch young in the tammar by removing a 0·70-gm. 'joey' and segregating the female from all males. Unfortunately, initial examination of the pouch was made 62 days after the removal of the first 'joey'.

During the course of the present work on marsupial macropods we have found blastocysts lying free in the uteri of two marloos (*Macropus rufus*) which both had 150-gm. 'joeys'. Apart from Carson's[1] initial observation this appears to be the only reported evidence for delayed birth in this species.

We acknowledge financial assistance from Western Australian University Research Grants and a generous grant for marsupial research from the Commonwealth Scientific and Industrial Research Organization executive.

ENTOMOLOGY

Time of Feeding in Relation to the Toxicity of a Stomach Poison to the Desert Locust

PEARSON[1] first showed that the stomach toxicity of dieldrin to fifth-instar hoppers (nymphs) of the desert locust (*Schistocerca gregaria* Forsk.) was increased by a period of starvation after treatment and suggested that this was due to variation in the rate of passage of the poison through the gut. We have confirmed and extended his observations and are directing attention to them because there appears to be little published information on the effects of starvation on the toxicity of stomach poisons to insects[2] although attention has been given to the effects of the diet fed to insects before they are used for experimental purposes[3].

When insects are fed with poisons applied by methods (for example, the poisoned sandwich method) other than those utilizing a poisoned medium there are usually time intervals between removal of the insects from their normal food, consumption of the poison, and resumption of normal feeding. In practice the insects are usually starved before an experiment, in order that they will readily accept proffered food and/or poison[2]. When the time-intervals are variable and of the duration of several hours they can affect the rate of passage through the gut of small quantities of food such as those that comprise a 'sandwich' containing poison.

A batch of fifth-instar nymphs, 4–7 days after moulting, was randomly divided into three groups. Two of the groups were deprived of food for 24 hr. Each insect in all three groups was then fed a small quantity of fluorescent powder ('phosphorescent powder, green', supplied by Rex Campbell, Ltd.) applied in gum to a small piece of grass. Immediately after eating this material two of the groups, including one of those previously starved, were then supplied with abundant fresh grass. The three groups of insects therefore received different treatments: group I was starved before dosing and fed after, group II was fed before and after, while group III was starved before and after. The fæcal pellets produced by each group in successive hours after ingestion of the indicator substance were counted. Each pellet was then broken up in about 1 ml. of water and examined in ultra-violet light, when any granules of the indicator present were clearly visible. The results obtained are shown in Table 1.

Table 1. TOTAL NUMBER OF FÆCAL PELLETS AND NUMBER CONTAINING INDICATOR AT DIFFERENT TIMES AFTER DOSING (PER GROUP OF 10 HOPPERS)

Treatment group	Hours after dosing				
	0–1	1–2	2–3	3–4	5–6
I	7/19	23/31	14/30	18/32	5/36
II	*	2/22	8/18	15/16	16/30
III	0/3	0/3	0/4	3/3	7/7

* Owing to difficulty in making these insects feed, no estimate can be given for this period.

It will be seen from Table 1 that the proportion of pellets containing the indicator depends on the treatment given. However, the quantity of indicator substance in each pellet was very variable, and rough quantitative estimates were made visually of the amount lost per hour. It was estimated that 80 per cent was lost in less than 2 hr. in group I, in 4–5 hr. in group II, and in 7 hr. in group III.

In further experiments the same range of doses of the insecticide dieldrin was fed to each of two groups of hoppers which had been starved for a period of 24 hr. The insecticide was applied to a small portion of a blade of grass, and within 15 min. of eating this the hoppers of one group were supplied with abundant freshly cut grass. No deaths occurred within five days among the 56 insects in this group. The second group was kept without food for a further 24 hr. after dosing and a total of 48 deaths occurred during the next five days from the 55 insects that were dosed. These results corresponded to *LD*50's of $\gg$ 4·8 and 0·79 μgm./gm. respectively. In the second experiment similar results were obtained, that is, *LD*50's of $\gg$ 4·8 and 0·95 μgm./gm.

Pearson's toxicity results clearly fit in with these findings. His normal treatment most nearly followed group I above, since his insects "were not fed on the previous evening" but were fed immediately after dosing, while his starvation treatment was equivalent to group III. As a result of the different treatments the resistance of the insects fed immediately after dosing was increased 1·5–2·8 times.

It is interesting to note that what might appear to be a convenient laboratory procedure may yield very variable results. For example, locusts may be deprived of food for 24 hr. before a stomach toxicity experiment is due to be carried out and then given the poisoned food. Later, when convenient, they are supplied with abundant grass ; if this occurs immediately after the poison is consumed, the toxicity will be very much less than if there is a delay of a few hours, as may well occur when a large series of individuals is being treated.

In the field, Ellis and Ashall[4] found that in some cases hoppers exhibited a noticeable diurnal rhythm in feeding, there being least feeding during the 6 hr. after dawn, and most between 1600 and 2200 hr. It is thus probable that when dieldrin is sprayed on vegetation, a technique being used on an increasing scale[5] for locust control, its toxicity will vary with the time of day at which it is eaten.

Fertilization of Eggs of the Desert Locust by Spermatozoa from Successive Copulations

In the desert locust (*Schistocerca gregaria* Forsk.) copulation occurs frequently, although once fertilization has taken place further copulation appears to serve mainly as a stimulant to egg-laying and to be unnecessary for renewed fertilization[1]. An interesting problem arises as to whether, after a second copulation, eggs are fertilized by sperm from the first or the second copulation. The following experiment was devised, using an albino stock of *Schistocerca*. It has been shown previously that crosses between albino and normal adults show a Mendelian pattern of inheritance, in which albinism is recessive[2].

Four pure albino females were kept in isolation in cages, and when they were sexually mature an albino male was introduced into each cage for 24 hr. and then removed. Subsequent oviposition produced averages of 60–80 young locusts per egg pod, and these included both males and females, showing that copulation had taken place. After each albino female had laid two egg pods, from which only albino hatchlings resulted, a normal-strain male was placed with each of the females and then removed after 24 hr. All subsequent egg pods produced young locusts that were normal in appearance, to the almost complete exclusion of albinos. In fact, out of 1,033 eggs that hatched, 1,028 were normal and five were albino. In a further experiment, the same procedure was adopted except that the albino female was fertilized first by a normal male and then by an albino ; the progeny of the first two pods were all normal in appearance, but after the second copulation all, without exception, were albino.

It is known that spermatozoa can fertilize eggs at least ten weeks after the last copulation[1], but from the present experiments it appears that a second injection in some way prevents further use of the previous spermatozoa. This is evidently not due to competition between a more and a less virile strain, as it occurred whether the albino or the normal male was used second. Whether the first spermatozoa were inactivated in some way, or even killed, by the second, or the second spermatophore mechanically prevented the first spermatozoa from reaching the eggs, cannot be deduced from these observations.

OCEANOGRAPHY

Manganese Deposition on the Shells of Living Molluscs

Recently, there has been a renewal of interest in manganese deposition on the sea bed, particularly that brought about by biological rather than inorganic processes[1–6]. During the past fifty years[1–14] various theories have been put forward concerning the method of manganese deposition, yet the only measurements on the rate of deposition are those of Petterssen[11,12], and Buttler and Houtermans[13] on manganese nodules of deep-sea origin. These authors give a rate of the order of 1 mm. in 1,000 years.

During a survey of the sublittoral fauna of the Clyde sea area from 1949 onwards, it has been observed that the shells of many living molluscs are encrusted with a black deposit. In particular, this was the case of molluscs taken from muds and sandy-muds at depths of 15–105 fathoms. Although this has been recorded before[7–9,15], past analyses were limited to nodules, and deposits on stones and empty shells. While many species of living molluscs in the Clyde have manganese deposited on their shells, it is significant that deposits are more common and much heavier on shells with a dull, matt periostracum than on those with a glossy periostracum.

Yellow, and olive-coloured shells seem to be most affected, although deposits occur on shells of other colour. Thus species of *Nucula* clearly show the difference between glossy and matt surfaces, for while matt *N. sulcata* and *N. nucleus* may be completely covered with the black deposit (none of the older shells of many hundreds examined is free of deposit), glossy *N. turgida* and *N. tenuis* from the same substratum and of the same age rarely show any deposit. When present in the two latter species the deposit is confined to a small, thin film at the umbo. Although the list is not exhaustive, other species noted for their black deposit are *Corbula gibba*, *Venus casina*, *Nuculana minuta*, *Cyprina islandica*, *Mysella bidentata*, *Glycymeris glycymeris*, the underside of *Pecten maximus* and *Chlamys septemradiata*, *Natica alderi*, *Neptunea antiqua* and the tips of *Dentalium entalis*. All these species live at or close to the surface of the bottom sediment.

Analysis confirms that a high percentage of manganese is present in the deposits on these shells, far more than in the bottom sediment in which they live (Table 1). The percentage of manganese is close to that estimated for nodules from the same area. As figures for the rate of growth of *Nucula* species are available[16] micrometer measurements of the thickness of the deposit at the umbo give some idea of the rate of deposition. Shells of *N. sulcata* and *N. nucleus* less than 5 years old have a thin coating that is not easily measured; but the deposit on the dorsal side of shells more than 8 years old can be easily flaked off and its thickness determined. The results are shown in Fig. 1. It will be seen that, exceptionally, a deposit 1·27 mm. thick can be laid down in 12 years, but most fall in the range 0·30–0·70 mm. in 17 years (1 mm. in 25–60 years). It is possible that some of the deposit may be rubbed off by the movements of the *Nucula*, although the umbo, which is always affected, probably projects above the surface of the mud and so avoids friction with the substratum. Maximum deposition of manganese occurs on shells and non-living loci at the surface of the bottom sediment[6]. The deposit on living molluscs is remarkably compact and hard, perhaps suggesting origin from biological activity rather than the adsorption of precipitated particles. The possible origin of the Clyde nodules and deposits from streams flowing off manganese and iron-rich bogs cannot be neglected, although a higher percentage of manganese in the bottom sediments might be expected. Such an origin was discussed by Murray and Irvine[9]. The figures given above suggest that the largest nodules (approx. 6 mm. diam.) in a sample taken from the Minard Narrows (L. Fyne) are 75–190 years old. This is in contrast with 3,000 years for deep-sea nodules of the same size.

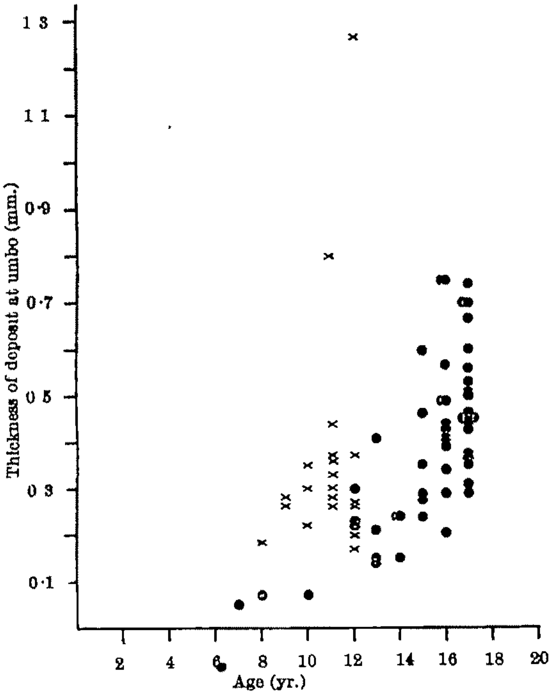

Fig. 1. Rate of manganese deposition on the shells of living *Nucula nucleus* (×) and *N. sulcata* (●)

Table 1

Locality	Manganese (per cent)
Nodules from Minard Narrows (Clyde)	18·7
Nodules from other sources (Goldberg) (ref. 3)	10·8–24·15
Substratum Arran Deep (Clyde) 60 fm.	0·1
Substratum North Sea 30 fm.	0·1
N. sulcata, Cumbrae Deep (Clyde), 60 fm.	8·5
N. sulcata, Arran Deep (Clyde), 60 fm.	17·9
Astarte montagui, Inverkip Bay (Clyde), 25 fm	11·5

I am indebted to Dr. A. Gilchrist of the Metallurgy Department, King's College, Newcastle upon Tyne, who kindly carried out the manganese estimations.

PSYCHOLOGY

Scoring of a 'Steadiness' Test

A TEST of 'steadiness' has been used in this Department as a class experiment, in order to illustrate the importance of the 'double blind' principle in the design of controlled clinical trials. The apparatus of Seashore and Adams[1] was chosen. Steadiness is measured as the ability to hold a metal stylus in position for a fixed period within holes of graduated diameters, drilled in a metal plate, without allowing the stylus to come into contact with the sides of the hole. An index of steadiness is obtained by multiplying the contact times for each hole by arbitrary factors related to the hole diameters, and summing the result.

The timer used in this experiment was constructed from 'Add-on' dekatron units (Ericsson Telephones, Ltd., Beeston, Nottingham). A time signal (100 p.p.s.) is fed into the counting device through the input selector. With the 'count' key fixed in the reset position, the counter is set up for automatic starting and resetting through the socket of the terminal dekatron unit, the connexions being made by means of a 12-pin miniature Jones plug. The counter starts operating when the terminal *PLA*9 is earthed and is reset by removing the earthing temporarily from *PLA*10. In the 'start' circuit there is a Post Office 'Uniselector' driven by 40 V. d.c. pulses from a time clock. The contacts in the 'Uniselector' are connected in such a way that, after a 2·5-sec. interval, the 'start' circuit is completed for a period of 10 sec. The 'start' circuit also contains a high-speed relay, which is actuated by a 40-V. d.c current, 'made' when the stylus touches the sides of the hole. The relay closes the 'start' circuit and the counter operates. When the stylus is not touching the edge of the hole, the relay contacts are open, and the counter stops. Readings are thus obtained directly (in units of 0·01 sec.) of the time in a 10-sec test period during which the stylus is in contact with the hole.

Experiments were carried out on 58 students aged 19–32, 54 of whom were aged 23 or less. The test procedure was as follows. Students were divided into pairs, one acting as subject and the other working the apparatus. The controlled testing situation for the stationary position recommended by Seashore and Adams[1] was adopted, with the exception that the apparatus allowed each subject a 2·5-sec. interval to become accustomed to the operation of the timer. A test run consisted of four replicate trials, each comprising one reading apiece in the five holes the dimensions of which are given in Table 1,*a*. After a control run, the subject swallowed a tablet, which might contain either a stimulant drug or a placebo. An hour later a further test run was carried out. In the conditions of the experiment, a 'placebo effect' could be demonstrated, contact times being significantly decreased ($P < 0{\cdot}001$) at the second test run. No learning or fatigue effects during either run could be demonstrated.

Table 1. CORRECTION FACTORS FOR A 'STYLUS AND HOLE' STEADINESS TEST

Results of 232 observations on 58 subjects. To obtain a standardized score the contact times for each hole are multiplied by the appropriate correction factor and the results are summed

(*a*) Hole diameter (1/64 in.)	12	11	10	9	8
(*b*) Mean contact time in a 10 sec. test period (0·01 sec)	224·9	97·7	46·0	29·2	20·8
(*c*) 1/(*b*) × 100	0·445	1·023	2·174	3·425	4·808
(*d*) Correction factors (Spaeth and Dunham, ref. 2)	0·5	1	5	10	20
(*e*) Correction factors based on (*c*)	1	2	4	7	10

Mean contact times for each of the five holes were calculated from the control runs, comprising 232 readings in each hole (see Table 1,*c*). Some arbitrary assumption is necessary to render comparable the five respective means. At first sight it would appear simplest to use multiplication factors proportional to the reciprocals of the observed mean contact times so that, after correction, the readings from each hole would give, on the average, the same numerical result. The correction factors recommended by Spaeth and Dunham[2] (Table 1,*d*) do not obey this relation. An alternative series of integer factors which possesses approximately the desired property is given in Table 1,*e*. It is possible, however, that investigation of the wave form of upper limb tremor in relation to the geometry of the apparatus might show that some other basis for correcting the reading was preferable.

I wish to thank the students in the Pharmacology and Statistics Departments of the University of Sheffield who took part in the experiments, Mrs. W. M. Wright for help and statistical analyses and Dr. D. R. Wood for advice in constructing the apparatus.

STATISTICS

Fitting ν Linear Relations to n Variables all liable to Error

IN a recent communication, B. E. Kelly[1] has directed attention to W. E. Deming's sadly neglected monograph "Statistical Adjustment of Data" (1943), and comments that Deming's procedure leads to the solution found by P. A. Wayman[2] for the best-fitting straight line to a series of observations of two variables both subject to variable error. This is not correct: Deming neglected the variation of his weighting factor W_i with the slope of the fitted line, and his result (p. 180) is a weighted regression. We have re-examined the problem of multivariate linear relations: when both variables are subject to independently variable errors we obtain a result the bivariate case of which agrees with Wayman's (which so far as we can find had not previously been described); when the ratio of the standard deviations of error in the several variables is constant for all sets of measurements, we find that for n variables connected by ν linear relations the best-fitting $(n - \nu)$-flat is defined by the ν latent vectors of the covariance matrix corresponding to its ν smallest latent roots; and we have been able to find a procedure suitable when not all the variables were measured at every point (a situation very common in studies of the correlation of chemical composition and physical properties of minerals). Certain non-linear relations of mineralogical importance are under investigation.

D. E. Barton and C. L. Mallows[3], discussing methods of curve-fitting other than least-squares, mention J. Berkson's method[4] of the 'controlled variable'. This method is based on the assumption that if in a series of experiments we adjust one variable as nearly as we can to a series of pre-selected 'control' values (one measurement at each) it will be proper to assume that the error of measurement is independent of the observed value, but that if no such 'control' is attempted the error of measurement is, necessarily, independent of the true value and not of the observed value; we are unable to find any justification for this postulate, and believe this procedure to be wholly invalid.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, February 1

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. E. G. Massey Collier: Presidential Address.

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. K. D. B. Johnson: "Industrial Separation of Isotopes".

Tuesday, February 2

Plastics Institute (at the Wellcome Building, 183–193 Euston Road, London, N.W.1), at 4 p.m.—Symposium on "Preplasticizing in Injection Moulding".

Institution of Electrical Engineers, Measurement and Control Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. P. Vigoureux: "Development of the Formulæ of Electromagnetism in the M.K.S. System".

University of London (at Imperial College of Science and Technology, South Kensington, London, S.W.7), at 5.30 p.m.—Prof. F. C. Tompkins: "Superficial Chemistry and Solid Imperfections".* (Inaugural Lecture.)

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. Paul Fourman: "Magnesium Metabolism in Man".* (Seventh of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on February 4, 9, 11, 16, 18, 23, 25 and March 1).

University of London (at the Middlesex Hospital Medical School Mortimer Street, London, W.1), at 5.30 p.m.—Dr. Honor B. Fell "The Experimental Transformation of Cells"*.

British Interplanetary Society (at Caxton Hall, Westminster, London, S.W.1), at 7 p.m.—Mr. A. Wilson: "The Use of Reinforced Plastics in Rockets".

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. H. H. Pearcey: "Suppression of Shock-induced Separations by Boundary Layer Control".

Wednesday, February 3

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Mr. Clifford Paine: "Modern Dyes" (Sir William Jackson Pope Memorial Lecture).

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5 p.m.—Mr. R. L. Plackett: "Models in the Analysis of Variance".

Society of Chemical Industry, Heavy Organic Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. D. J. Hadley: "The Preparation and Use of Nitriles".

Society for Analytical Chemistry (joint meeting with the Oils and Fats Group of the Society of Chemical Industry, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Meeting on "Spectroscopic Investigation of Fats".

Thursday, February 4

Royal Society (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion on "The Results of the Royal Society I.G.Y. Expedition" opened by Sir Graham Sutton, F.R.S.

Physical Society, Optical Group (at Imperial College, London, S.W.7), at 2.30 p.m.—Dr. H. C. King: "The London Planetarium"; Mr. G. M. Sisson: "Present Plans for the Isaac Newton Telescope".

Institution of Naval Architects (at 10 Upper Belgrave Street, London, S.W.1), at 4.45 p.m.—Scientific Papers.

University College (in the Physiology Theatre, Gower Street, London, W.C.1), at 5 p.m.—Dr. Elizabeth Work: "The Mucopeptides of Bacterial Cell Walls".* (First of two lectures in Biochemistry. Further lecture on February 11.)

Institute of Refrigeration (at the Institute of Marine Engineers, The Memorial Building, 76 Mark Lane, London, E.C.3), at 5.30 p.m.—Mr. J. M. Buist and Mr. R. Hurd: "Polyurethane Foams—Their Contribution to Heat Insulation".

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. J. H. Gridley: "The Shielding of Overhead Lines against Lightning".

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. B. Verney: "Some Aspects of the Renal Excretion of Water and Electrolytes".* (Eighth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on February 9, 11, 16, 18, 23, 25 and March 1.)

Friday, February 5

Institution of Electrical Engineers, Medical Electronics Discussion Group (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Computers in Medical Use" opened by Dr. R. A. Buckingham and Dr. J. M. Tanner.

Society of Dyers and Colourists (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Mr. L. Cotton and Mr. J. Wardle: "Dyeing and Finishing of 'Courtolon' Nylon in Relation to Its Yarn Properties".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. J. F. Danielli, F.R.S.: "Some New Approaches to Inheritance and Evolution" (The Woodhull Lecture).

Saturday, February 6

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Miss Maitland Howard: "Cats and Magic".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Pure Mathematics, and an Assistant Lecturer in Applied Mathematics in the Department of Mathematics; and an Assistant Lecturer in Applied Mathematics in the Department of Theoretical Mechanics—The Registrar, The University, Nottingham (February 6).

Chemist and Bacteriologist (with an honours degree in chemistry, member of the Royal Institute of Chemistry, and extensive experience of water treatment and examination)—Fylde Water Board, Sefton Street, Blackpool (February 8).

Librarian (with a degree or recognized qualification in librarianship, experience in a special library, preferably serving a research organization), to take charge of the Library at the Central Electricity Generating Board's Research Laboratories at Leatherhead, Surrey—The Personnel Officer, Central Electricity Generating Board, 24/30 Holborn, London, E.C.1, marking envelope "Confidential Ref. N/9" (February 8).

Assistant Lecturer in British Archæology—The Registrar, The University, Leicester (February 12).

Assistant Lecturers in Chemistry, Physics and Zoology—The Registrar, The University, Leicester (February 12).

Assistant Librarian (man or woman graduate)—The Registrar, The University, Leicester (February 12).

Lecturer or Assistant Lecturer (with a good honours degree and experience in teaching and research) in Mathematics at the University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (London and Malaya, February 12).

Principal of Cornwall Technical College, Camborne—The Secretary for Education, County Hall, Truro, Cornwall (February 12).

Lecturer in Education Psychology—The Registrar, The University, Liverpool, quoting Ref. CV/T (February 13).

Research Assistant in the Postgraduate Department of Applied Mechanics—The Registrar, The University, Sheffield (February 13).

Research Assistant (with a good degree, and preferably a higher degree in physics, chemistry, engineering or ceramics) in the Houldsworth School of Applied Science, to work on the high-temperature properties of certain ceramics of potential interest as engineering materials—The Registrar, The University, Leeds 2 (February 13).

Gulbenkian Research Fellow, to investigate certain aspects of the teaching of physics or chemistry in schools—The Registrar and Secretary, The University, Bristol (February 15).

Lecturer or Demonstrator in Chemical Pathology, for duties divided equally between original investigation and supervision of the hospital laboratory—The Registrar, The University, Leeds 2 (February 15).

Reader in Applied Mathematics—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (February 15).

Editorial Assistant, Assistant Experimental or Experimental Officer, in the Publication Section, Road Research Laboratory, D.S.I.R., Harmondsworth, Middlesex, for work involving the editing and preparing for publication articles to technical journals, official booklets issued by the Laboratory, etc.—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.21/0A (February 19).

Junior Lecturer (preferably with the ability to share in the teaching of basic courses in psychology) in Education—The Registrar, Trinity College, Dublin (February 22).

Chair of Zoology at Westfield College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 25).

Lecturer in Petrology in the Department of Geology—The Secretary, The University, Edinburgh (February 27).

Turner and Newall Research Fellows in Engineering, Inorganic Chemistry, Physics and allied subjects—The Registrar, The University, Manchester 13 (February 27).

Assistant Lecturer or Lecturer in Animal Husbandry in the Faculty of Veterinary Science—The Registrar, The University, Liverpool, quoting Ref. CV/T (February 29).

Leverhulme Postgraduate Fellows (3), 2 in the Faculty of Science and 1 in the Faculty of Engineering—The Registrar, The University, Liverpool, quoting Ref. CV/T (March 1).

Chair of Biochemistry at King's College, Strand, London, W.C.2—The Academic Registrar, University of London, Senate House, London, W.C.1 (March 2).

Lecturer or Assistant Lecturer in Botany at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 5).

Lecturer or Assistant Lecturer in Physics—The Registrar, The University, Southampton (March 5).

Imperial Chemical Industries Research Fellows in Chemistry or Physics—The Registrar, The University, Hull (March 7).

Associate Professor of Mathematical Statistics at the University of New England, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, March 12).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Engineering, Pharmacology or Physics—The Secretary, The University, Aberdeen (March 12).

Reader or Senior Lecturer in Agricultural Chemistry, and a Lecturer in Animal Physiology in the Faculty of Agriculture, Makerere College, University College of East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 15).

Senior Lecturer (graduate of a British university or equivalent qualifications and experience appropriate to the post) in Physics; and an Assistant Lecturer (with a good honours degree in physics and preferably some experience of teaching and research) in Physics at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong and London, March 15).

Lecturer (preferably with a special interest in the field of transition elements or of complexes) in Inorganic Chemistry—The Secretary, The Queen's University, Belfast (March 18).

Lecturer and an Assistant Lecturer (preferably with a research interest in the application of mathematics to some engineering subject) in Engineering Mathematics—The Secretary, The Queen's University, Belfast (March 30).

Isaac Wolfson Research Fellow (suitably qualified graduate aged 24–35, either British subject (from any Commonwealth country) or Israeli citizen) in Metallurgy—The Principal, St. Edmund Hall, Oxford (April 23).

Associated Electrical Industries Fellow for Research in the Department of Physics—The Secretary-General of the Faculties, The Old Schools, The University, Cambridge (April 30).

Assistant Lecturer in the Department of Nutrition—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

Associate Dean of the School of Art and Sciences; Professor of Electrical Engineering; Professor of Engineering Physics; and a Professor of Mechanical Engineering, at the Middle East Technical University, Ankara—Room 139, Foreign Office, London, S.W.1.

Chemist (with a good honours degree in agricultural chemistry or chemistry and a knowledge of field experimentation) in the Department of Agriculture, Uganda, for research on soil fertility problems connected with tropical crop rotations, manures and fertilizers—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/9/09/T.

Lecturer (well qualified physicist, with research, industrial or teaching experience) in the Science and Mathematics Department—The Principal, Rugby College of Engineering Technology, Eastlands, Rugby.

Lecturer (with a degree in chemical engineering or metallurgy) in the Department of Metallurgy, to teach the engineering principles of extraction metallurgy, particular attention being given to the effects of heat and mass transfer and fluid flow on the design and operation of metallurgical processes—Prof. F. D. Richardson, Department of Metallurgy, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7.

Lecturer (with an honours degree in chemistry, with postgraduate experience of academic or industrial research) in Organic Chemistry—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

Master to teach Physics in the Upper School, including Sixth Forms—The Headmaster, Ellesmere College, Shropshire.

Physicist, Senior grade (with at least five years experience in radiotherapy physics)—The Group Secretary, Mount Vernon Hospital, Northwood, Middlesex.

Research Assistant (preferably with an honours degree in zoology or medical sciences, and a knowledge of German) in the Department of Anatomy, for work mainly on the central nervous system—The Secretary, University College, Gower Street, London, W.C.1.

Research Entomologist (male, with a good honours degree in natural science, or a degree in agriculture with honours in entomology, and experienced in entomological research) in the Department of Agriculture, Nyasaland, to assist with investigation of cotton pest problems in the Federation of Rhodesia and Nyasaland—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD./63/4/016/T.

Research Fellow (with a good degree in electrical engineering, physics or chemistry and some research experience of vacuum systems) in the Department of Electrical Engineering—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1.

Scientific Assistant, to assist an entomologist developing a technique to control *Culicoides impunctatus* in Scotland—R. Parish, B.Sc., Department of Zoology, University of Edinburgh, West Mains Road, Edinburgh 9.

'TEEN-AGE' EDUCATION IN ENGLAND

IN March 1956 the Minister of Education asked the Central Advisory Council for Education (England) to advise him on the education of boys and girls between the ages of fifteen and eighteen. Under its chairman, Sir Geoffrey Crowther, the thirty distinguished members of the Committee have produced a report* which is worthy to take its place alongside such well-known predecessors as Hadow, Spens, Fleming and Norwood. It provides an all-embracing survey of the educational services available to the 'teen-age' population of England and Wales, as well as a penetrating analysis of the very considerable deficiencies in those services.

The Report has clearly been drafted by more than one hand, but by far the larger portion of it is written in the simple prose which would bring commendation from a Churchill or a Gowers. It is a report which, apart from the great importance of its subject-matter, asks to be read because of the attractive way in which it is presented.

Although the main recommendations are likely to stir up discussion which may at times become acrimonious, even the most robust critics of the Report would wish to endorse the Minister's gratitude to Sir Geoffrey and his colleagues for a Herculean task well done.

The Report is concerned with four sectors of educational provision for boys and girls between the ages of fifteen and eighteen—it is not concerned with the youth service, which is being examined separately by the Albemarle Committee—but will, almost certainly, become widely known for two main recommendations. These are the proposals to extend the age at which all children must remain at school—the age would be sixteen and the operative year would be between 1966–67 and 1968–69; and the introduction of county colleges according to a phased programme which would be completed within 15–20 years from now. There are, however, a number of other recommendations which could vitally affect the quality of education provided for teen-agers and which deserve close study. Few will quarrel with them, and in time nearly all should be implemented. Among them are the place of examinations in secondary modern schools, provision for those who leave full-time education at the age of sixteen and who require continued education with a vocational bias through day-release or sandwich courses, the way to combat specialization in school sixth forms (which the Council is prepared to support provided it does not mean over-specialization), the kind of teachers who will be required for the county colleges and the way to find and develop them. The cost of the required reforms would put no unbearable strain upon the Exchequer.

The decision to recommend that the school-leaving age should be raised in the late 1960's was based upon careful analysis of the place of education in a changing world, particularly that relating to secondary education. Whereas in 1894 only about 4 per cent of all boys and girls aged fourteen or fifteen were in school, and only 1 per cent of those aged sixteen and seventeen, to-day about two-fifths of all boys and girls aged 15–17 have education either full-time or for one day a week. Of the 2½ million children in maintained secondary schools, however, only 320,000 of them are aged fifteen or more; the Committee is concerned that the rest of the two million who could benefit should be given opportunities in full-time education as quickly as possible. In 1894 such a proposal would have been regarded as disastrous by parents whose children were regarded as winners of the extra bread which made life tolerable for the family. To-day, few families cannot support their children throughout a longer school education, a situation brought about by marked changes in economic social life of Britain. Compared with 1938, the community is about one-third richer in material wealth. The larger part of the rise in the national standard of consumption has been in the lower income-groups, a change reflected in the physique and health of school-children during the past twenty years. Other influences which make it easier to support a longer school life for children are earlier marriage, earlier child-bearing within marriage, smaller families, longer expectation of life and more opportunities of paid employment for married women.

The position of girls in the age-group studied has probably changed even more than that of boys. Child-bearing and child-care now represent a break in employment for married women rather than an end to it. This has important consequences for teaching as well as other careers. It points to the need for an education which encourages girls to qualify before marriage for careers and to develop interests which they can resume in later life. The early age of marriage points to a radically different concept of how girls of seventeen and eighteen should be treated and educated; more than 4 per cent of the girls with whom the report is concerned are married women.

The pressure of economic change bears upon school life in a number of ways. The earnings of young people have risen much faster in proportion than those of adults, and those who remain at school have to resist the lure of a high immediate wage; and to reconcile themselves to a lower earning capacity, until they are more than twenty years of age, than that enjoyed by those who leave at fifteen. It is evident, however, that they then catch up and go well ahead. Parallel with the need to stay at school as long as possible to obtain long-term economic advantages, there is growing stress on the need for specialist qualifications and for a good general education to secure entry into an increasing number of occupations. This tendency may be reinforced by the fact that the proportion of young people to the whole population of working age is going to rise again after a long period of decline.

---

* Ministry of Education. 15 to 18: A Report of the Central Advisory Council for Education (England). Vol. 1: Report. Pp. xxxi+519. (London: H.M. Stationery Office, 1959.) 12s. 6d. net.

It is within this framework that the Committee sets its pattern for the future of teen-age education in the Britain of the future—for what is done in England is likely to be followed by Wales and, probably, Northern Ireland and Scotland. Education is regarded both as a duty that the State owes to its citizens—as part of the Welfare State—and as a means of increasing the economic efficiency of the whole community, and thus as a form of productive national capital investment. The Council welcomes the rapidly growing tendency for many secondary modern scholars to stay at school voluntarily until sixteen and hopes that, by 1965, about half the total numbers of secondary modern boys and girls will be taking extended courses beyond the age of fifteen. For the pupils for whom the General Certificate of Education examinations at Ordinary Level are unsuitable, the Committee recommends that external examinations should be developed experimentally on a regional or local basis.

With this assessment of the state of education and with these recommendations there will be few dissentients. With the major recommendation, that all children should stay at school until they are at least sixteen years of age, there is likely to be considerable disagreement. The Committee might well argue that it was only seeking to justify a decision of Parliament which is already on the statute book. There are many who would argue that all the experience with the lower streams of secondary modern school children since the Butler Act of 1944 should have led the Committee to recommend either that this section of the Act be repealed or postponed almost indefinitely, until much more pressing reforms to improve both the quality and quantity of British educational services be undertaken. Young people of England and Wales would gain much more if the extra teaching and material resources that will become available over the next decade were used to develop nursery schools, reduce the size of primary school classes, improve the quality of education for those taking City and Guilds and National Certificate courses—which in some local technical colleges is unbelievably bad and explains why many students fail to stay the course—to introduce speedily the much-heralded county colleges, to provide hostels so that university students may begin to live university lives and to develop day-release facilities for adult workers in industry.

The more this Report is studied the more one realizes how false a deduction is drawn from such lofty principles. The case for providing facilities for those two-thirds of secondary modern children who voluntarily wish to stay at school until they are sixteen or more and whose parents are equally keen is well made out. The case for compulsorily keeping those in school for whom the extra year (to fifteen) has already proved a burden to themselves and a source of frustration to those who try to teach them, appears to rest on the belief that 'Daddy-knows-best' and on the over-worked moral principle that what is good for some is good for all. Elsewhere in the Report we are told that the greatest number of juvenile delinquents is drawn from boys and girls who are in their last year of school, and that the desire to learn in many young people has only been awakened by their discovery at work of new ambition or personal inadequacy. All who have been concerned with *C* and *D* stream secondary modern youths at work will know how true this is, and would resist any attempt to inflict another year of misery on these unfortunate young people, for whom the academic approach has proved so inadequate in their development.

Here, as the reaction to the proposed raising of the school-leaving age has shown, they would be supported by all those teachers who teach day by day the scholars from lower streams of modern schools. These teachers frankly admit that they have been unable to find the way to interest and educate these boys and girls, and they believe that the only approach which is likely to be successful is through an integrated training scheme in a progressive firm with day-release facilities providing a clear vocational link with everyday work. It is a matter of regret that no member of the Crowther Committee teaches the lower streams in a modern school or deals with them directly in industry once they have left school. It is not without significance, however, that a strong minority of the Committee is far from happy about raising the school-leaving age for certain scholars who are physically or emotionally maladjusted to school life. They should persuade their colleagues to reconsider this controversial proposal and to take evidence from appropriate teachers in secondary modern schools, from industrial training officers concerned with the less intelligent type of existing school-leavers, and, above all, from the young people themselves not only when they are still at school but also six months after they have left.

Of the Committee's second main proposal—to introduce gradually a system of county colleges some fifteen to twenty years from now—the only disagreement will be the timing. The case for day-release was made out in 1918 and has not been contested. It was given a double blessing in 1944. When an important committee now reports that county colleges should come in time—after experiments in a few areas to gain experience and then by a spread region from region—it reveals either lack of conviction, lack of a sense of urgency, or the lack of moral courage to recommend that such a highly desirable reform is one about which Britain as a whole can no longer afford to procrastinate. To declare that more experience is needed before county colleges are developed nation-wide is scarcely complimentary to Bournville, Langside, Rowntree's, Boot's College or the day-continuation activities which are now so well established under local education authorities like Liverpool and others. To infer that the scheme should wait for fifteen-twenty years is less than kind to the boys and girls of to-day and the next generation. To imply that the country cannot yet afford county colleges is flatly contradicted by the Committee's own declaration that, despite the gain in the nation's wealth, we are proportionately spending no more on education—other than what is being done at the universities and in advanced technology—than we were in 1938. This is a bad reflexion on the use of the nation's resources and the amount we are prepared to spend on the education of our young people. Finally, the assumption that the country will have neither the teachers nor the material resources to introduce county colleges before the late 1970's must be set against all that has happened in the past twenty years. A Welfare State has been born in Britain, with health and social services of which we may be proud. The school-leaving age has been raised. Technical and university education have been transformed. Now with the nation's economic pulse beating strongly and steadily, the Crowther Committee asks the British people to wait twenty years before a generally agreed reform is introduced.

Despite major recommendations which are unlikely to get a smooth passage, this Report should be examined in its entirety. The section on specialization in the sixth forms of schools should be read by every university teacher, as well as headmasters and senior masters in secondary schools. The chapters on institutions and teachers should be made into a tutorial course for many members of local education authorities. Finally, because the Report has been specially prepared with the general public in mind, those concerned with mass communication media could perform a public service by presenting its main arguments and recommendations to as big an audience as possible. The Crowther Report will influence the quality of English education for many years to come.

THE BIRTH OF THE ROYAL SOCIETY

History of the Royal Society

By Thomas Sprat. Edited with Critical Apparatus by Jackson I. Cope and Harold Whitmore Jones. (Washington University Studies.) Pp. xxxii + 456 + 78. (Saint Louis, Missouri: Washington University, 1958.) n.p.

Of recent years American scholarship has made many contributions to the history of science in the seventeenth century, prominent among many universities concerned being Harvard, represented by Bernard Cohen and his school, and Washington, the "University Studies" of which include in their wide range this period. The latest of these "Studies", which appears at a time when the forthcoming celebrations of the tercentenary of the foundation of the Royal Society make it of particular interest, is a re-issue of Thomas Sprat's "History of the Royal Society", furnished by the two editors with an introduction and extensive notes.

Thomas Sprat, born in 1635, graduated at Oxford, where he made some stir as a poet but none as a follower of the newly established pursuit of experimental science. He was, however, taken by Wilkins into the circle of active promoters and partisans of the new learning and was duly elected a Fellow of the newly formed Royal Society in 1663, which was no warranty of scientific prowess, as evidenced by the fact that the poets John Dryden, John Denham and Edmund Waller were admitted at the same time. He had close personal relationships with many of the distinguished founders of the Society and it was their influence, no doubt, that led him to write his "History of the Royal Society", which, published in 1667, is a history of the foundation of the Society and a defence against the scoffers; the misunderstanders, such as Sorbière; and the classical and religious carpers. The full title runs "The History of the Institution, Design and Progress of the Royal Society of London, For the Advancement of Experimental Philosophy". Sprat wrote largely as an apologist; as he says in his "Advertisment to the Reader": "and the Third (part) chiefly contains a Defence and Recommendation of Experimental Knowledge in General: So that it is only the Second Book that peculiarly describes their Undertaking". This "Second Book" which, however, occupies considerably more than half the volume, contains accounts of various scientific concerns of the Society, including, in particular, the "Method For making a History of the Weather", by Robert Hooke.

The book, written in a clear and pleasing style, attracted considerable attention, went into several editions, and was translated into French in 1669. In 1825, de Clugny wrote of it and the Royal Society: "Sprat mérita de devenir membre de cette société, et fut chargé par elle d'écrire son histoire, lorsqu'il devint nécessaire de se concilier l'esprit du public, qui croyait voir dans toute assemblée quelconque des sociétés pour rétablir la suprématie du pape. Son *Histoire de la société royale* . . . triompha de tous les pamphlets qui furent publiés contre elle. Cet ouvrage a été san doute surpassé, quant aux faits, par Birch, et plus recamment par Thomson; cependant il est écrit avec tant de pureté et d'élégance, qu'il est encore recherché". The reference to the supremacy of the Pope is somewhat surprising!

The text in the issue now before us is a facsimile, actual-size reproduction of the text of the first edition of the book, and the "Introduction" discusses, clearly and with ample references, the circumstances which attended the publication of the book and the nature of its contents, as well as the style in which it is written. Among the notes, which bespeak wide reading, those on Stubbe's acrimonious attacks on the Royal Society are of particular interest. In a short appendix the origin and nature of these attacks are further discussed, with references which do not include, however, Harcourt Brown.

In the "Foreword" the editors remark that Thomas Birch's "History of the Royal Society" is 'crippled' for want of an index, a complaint with which every student of seventeenth-century science will wholeheartedly sympathize. In fact, no Ph.D. degree could be more serviceably earned than by the compilation of such an index which, if well done, would demonstrate the necessary scholarship. An important earlier "Washington Study", Richard Foster Jones's "Ancients and Moderns", is likewise robbed of its full value by lack of an index. It is remarkable, in view of their specifically expressed opinion concerning Birch, that the editors should not have provided Sprat with an index. It is to be hoped that, should a re-issue of the book be called for, which is not unlikely, an adequate index will be furnished.

E. N. DA C. ANDRADE

MICROBIAL VARIATION AND RUSSIAN EXPERIMENTS

Microbial Variation

Edited by V. D. Timakov. Translated from the Russian by G. H. Beale. Pp. x+202. (London and New York: Pergamon Press, 1959.) 40s. net.

THE book contains twenty-two papers by workers at the Gamaleia Institute of Epidemiology and Microbiology on the subject of 'directed variation'. The investigations described fall into two main groups: studies of the consequences of growing one bacterial species on killed cultures of a different species in an attempt to explain the formation of new species in bacteria; and examination of the changes brought about in organisms as a result of submitting cultures to the effects of antibiotics, bacteriophages, immune sera, etc., with the object of obtaining avirulent organisms capable of immunizing against pathogenic bacteria. The thesis put forward by Prof. Timakov in the introductory article is that organisms undergo variation under such conditions and that the nature of the variation can be directed by the environmental conditions imposed.

The more controversial material is contained in the first nine papers, concerned with the variation of an organism 'directed' by growth in the presence of dead cells of another species. Sufficient experimental detail is provided to allow some assessment of the significance of the results or to provide the recipes for attempts at reproduction of the experiments. In essence the experiments involve the growth of a large inoculum (10^{10} cells) of, say, *Escherichia coli* in a medium containing a suspension of killed cells (density 10^8–10^9 cells/ml.) of, say, *Salmonella breslau*. Transfers are then made at intervals of seven days (details of times and temperatures are not stated in all papers) and variants appear after 6–15 transfers. Variants isolated after 6–7 transfers are unstable and lose their 'new' properties on cultivation in normal media; variants isolated after the fifteenth transfer are stable and possess new, stable characteristics. Examination of the properties of these stable variants shows that they have acquired some of the characteristics of the killed cells on which they were grown. In the example cited, cells are obtained which are agglutinated by anti-*breslau* but not by anti-*coli* serum, and have become virulent. Other variants are found to have characteristics intermediate between those of *E. coli* and *S. breslau*. In his introduction, Prof. Timakov suggests that this is not the change of one species into another, since the *breslau*-like variant differs from *S. breslau* in being less able to produce infection when given orally; consequently, the experiments are said to demonstrate the production of a new species. It all depends on how you define a species, and there is considerable specious argument on this topic.

Such 'directed variations' are accomplished using various typhoid, paratyphoid, dysentery and coli-form organisms. The editor remarks that "Certain objections which are not without foundation have been raised in connexion with this work . . . some workers believe that the bacteria . . . with characters of *S. breslau* were nothing more than germinated heat-resistant forms of *S. breslau*". One wishes that more details were provided to refute this belief; we are simply told that the suspensions were tested for sterility over a period of from fourteen days to six months. No practical details of bacteriological technique or quantitative data for controls are given. It is possible that something akin to transformation might be taking place in these experiments, and one paper deals with the directed variation of *E. coli* grown in the presence of nucleoproteins from pathogenic bacteria, but the work of Griffiths, Avery, Macleod and McCarty is dismissed in three lines as "inconclusive as proof of the occurrence of inter-specific variation". There is little attempt to explain what might be happening in these experiments, other than to emphasize that the formation of new species can be directed in these various ways.

The book provides an interesting account of the work and views of certain Soviet biologists. Readers' reactions will be largely conditioned by their training and beliefs, but, at least, they now have sufficient data provided for them to attempt to direct variation for themselves.

E. F. GALE

NON-METALLIC BRITTLE MATERIALS

Mechanical Properties of Non-Metallic Brittle Materials

Edited by W. H. Walton. (Proceedings of a Conference on Non-Metallic Brittle Materials organized by the Mining Research Establishment of the National Coal Board in consultation with the Building Research Station (D.S.I.R.), and held in London, April 1958.) Pp. xi+492. (London: Butterworths Scientific Publications; New York: Interscience Publishers, Inc., 1958.) 90s.

THE variety of brittle materials is immense; some of them are heterogeneous even on a macroscopic scale, and some are anisotropic. Both features make their study difficult. Yet a knowledge of the properties of these materials is of great importance to a variety of industrial processes and it was with this idea in mind that the Mining Research Establishment of the National Coal Board and the Building Research Station organized a conference in April 1958. The Proceedings of this Conference present, probably for the first time, a series of papers which demonstrate the immense amount of work which is going on in this field and also emphasize the difficulties of elucidating the properties of brittle materials because of the presence of a large number of varying parameters. The format of the Proceedings in general follows the course of the conference.

At Session 1, "Strength in Compression, Tension, Bending and Shear" was considered and papers were presented giving experimental results on the strength of cubes of coal under uniaxial compression and under triaxial compression, the strength of bricks and a review of the micro- and macro-strength of glass. Other subjects considered were the strain-stress relations and breakage of rocks, of their properties in conditions of triaxial stress and also the porosity and strength of brittle solids with particular reference to gypsum. These papers show a real attempt to correlate experimental results with theory, but it must be appreciated that many of the derived formulæ must, for the present, represent only an empirical interpretation of the properties and that much work is still to be done before the course of changes induced by applied stress can be forecast with any degree of accuracy.

Session 2 was devoted to consideration of "Elasticity and Creep". Papers were given on the elasticity, creep, shrinkage and the effect of rate of loading on some mechanical properties of concrete. The strength of ceramic materials under impact testing and sonic testing, and the stress-strain relationships in heavy clay products were discussed, while the factors effecting the thermal shock resistance of high-temperature materials were also considered. Measurements of the rheological behaviour of coal, together with the measurements of its dynamic mechanical properties, were compared with the paper presenting the elastic and plastic properties of carbon and graphite.

In the third session the conference went on to consider "Dynamic Loading, Impact and Fragmentation". Here papers were presented on the exploratory tests on the strength of concrete beams under pulse loads, impact testing and roller bit penetration. The breakage of natural materials was considered generally and in detail with the fragmentation of explosive detonated in stone blocks and with the partition of energy in a blasting shot. From the coal industry, studies of the size distribution and relationship between dust formation and coal strength provided an alternative approach.

Session 4 was devoted to a consideration of the "Action of Tools". There was a basic paper on friction between coal and metal surfaces and the forces required to penetrate the brittle material with a wedge-shaped tool. This was followed by a paper on the effect of lateral pressure on the cutting of coal by wedge-shaped tools and a consideration of both the theoretical and practical aspects of coal ploughing.

The discussions which followed papers and sessions have been admirably condensed and the whole volume will be an important work on the shelf of all who are concerned with understanding the processes in which the properties of brittle materials have to be taken into account. DAVID TRAIN

CONSERVATION IN AMERICA AND AFRICA

Conservation of Natural Resources
Edited by Guy-Harold Smith. Second edition
Pp. xi+474. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1958.) 68*s*. net.

The Conservation of Natural Resources
By Richard C. Haw. Pp. 256+36 photographs. (London: Faber and Faber, Ltd., 1959.) 30*s*. net.

IN every part of the world, though in varying degrees, the now obviously rapid increase in population consequent upon the fact that the spread of the knowledge and practice of death control has outstripped knowledge and practice of birth control is forcing attention on the need to conserve or to use wisely all natural resources. In the second edition of "Conservation of Natural Resources" the editor, Guy-Harold Smith, repeats the warning, "every individual company, or organization must share in the task of preserving the resource base upon which the American economy has been built. What is needed is an enthusiasm and an understanding of the essential nature of resources and the measures necessary to save from wasteful destruction our national heritage." It may be claimed that conservation in America was a by-product of the great economic depression of the nineteen-thirties which happened to coincide with disastrous seasons producing dust-bowl conditions over vast areas. Although ghost-towns already spoke eloquently of the exhaustion of mineral riches, abandoned farms of the retreat from the 'frontier' or 'pioneer fringe', conservation became identified with the prevention of soil erosion. An America which had been taught to think in square-mile blocks had to realize that Nature abhors a straight line, and to find answers in contour ploughing, strip cropping, restitution of grass cover thoughtlessly ploughed or woodland unwisely cleared. Now conservation has come to mean much more. The sixteen authors of this survey cover in its eight parts the land (with soil, irrigation, and grassland), the forests, water, minerals, wild life, recreational resources (linked with the conservation of man) and so to national, state and local planning.

Prof. S. S. Visher has an interesting introductory chapter on the public domain. It is perhaps not commonly recognized that practically all United States territory, except for the closely settled land of the original thirteen States, has, at one time, been Federal property. Forty-one per cent was sold to individuals for cash, 27 per cent granted to homesteaders, 13 per cent given to the railroad companies, 12 per cent given to education authorities, 1 per cent for canals, leaving 6 per cent, mainly of wet lands, which passed into ownership of the States. In 1956 more than 400,000,000 acres remained or had reverted to public ownership, being a total not far short of that in improved farm land. Thus Federal and State authorities are able to give a lead to conservation in the national forests and the great grazing lands as well as in national parks and Indian lands. But on privately owned land there are conflicting interests. Individual success is still measured largely by wealth: the obvious temptation is the quick fortune from 'mining', whether it be of minerals, the soil, or the forests. Technological advances will take care of the future and with the present over-production of agricultural commodities, those who preach conservation or teach it in the universities have by no means a pre-converted audience. This fine book should serve them well.

Although with an identical title, Mr. Richard C. Haw's book is very different. He is an instructor in the Domboshawa Government School at Salisbury in Southern Rhodesia: he writes essentially of the African veld and of the vital, urgent, necessity of its proper management if Africa is to survive. He uses the University Farm at Salisbury West as an example of planned layout; chapters which follow are practical guides to surveying, soil conservation, manuring, reclamation, road construction and water conservation. It is significant that he, too, does not forget the importance of wild life. Since so much of the world's problem lands lies in the seasonally dry sub-tropics, Haw's book deserves a wide public in other continents. L. DUDLEY STAMP

THE ARMAMENT RESEARCH AND DEVELOPMENT ESTABLISHMENT

OPEN Days were held for the first time, during November 3–6, at the Armament Research and Development Establishment, Fort Halstead, Sevenoaks, Kent. This Establishment was part of the former Ministry of Supply and from November 23 has been part of the War Office. The recent changes in organization made in Government departments prevented the attendance of a Minister of the Crown, and the official welcome to visitors to the Open Days was extended by Lieutenant-General Sir John Cowley, controller of munitions.

The Open Days were planned with the object of inviting as guests a wide representative selection of people who had not previously had the opportunity of visiting the Establishment. Although security restrictions inevitably affected the scope of the exhibition, an excellent impression of the wide variety of work undertaken by the Establishment was afforded to visitors.

More than three thousand visitors attended the exhibition during the four days. During November 4–5 the visitors included Government officials and Service officers, representatives of Commonwealth countries, attachés at foreign embassies, members of local authorities, teachers at universities, technical colleges and schools, and representatives of industry. On November 6, the Establishment was open to families and friends of the staff. Previously, on November 3, the Establishment welcomed about fifty representatives of the national, local and technical Press and of sound and television broadcasting services. It was evident that the exhibition attracted very considerable interest from the general public.

The Armament Research and Development Establishment was created on January 1, 1955, by the amalgamation of the Armament Research Establishment and the Armament Design Establishment. The director of the Establishment is Dr. D. H. Black. The work of the first-named Establishment was surveyed in a previous article in *Nature*[1]. Up to the end of the Second World War, the history of the Armament Research and Development Establishment and its predecessors is essentially the story of the development of high-explosive munitions. The post-war years have brought considerable changes in the work undertaken. Under the direction of Sir William Penney, the development of Britain's first atomic bomb was undertaken within the Armament Research Establishment organization at Fort Halstead. This project led to the formation of the Atomic Weapons Research Establishment at Aldermaston, now a part of the United Kingdom Atomic Energy Authority. The part played by conventional weapons has been greatly affected by the development of nuclear explosives and weapons. The Establishment continues to undertake highly important work on conventional explosives and weapons, but has also extended its responsibilities to newer branches in the armament field.

The Establishment undertakes research, and designs and develops weapons and ammunition for all three Armed Services. Equipment for which it is responsible is extremely diverse; this includes guns together with their mountings and ammunition, fuses, small arms and their ammunition, mines and pyrotechnics. The Establishment is also concerned with work on guided weapons. Much basic research, both theoretical and experimental, is pursued. This research is not always immediately related to particular weapons, but often leads later to applied research aimed at the design, development or improvement of specific weapons. Basic and applied research are undertaken in a wide variety of fields; these include high explosives, ballistics, metallurgy, radiography, electronics, electronic computers, and the mechanics of fluids and solids. Much of the research done falls within the ambit of the physical sciences, and applications outside the armament field often occur.

More than a hundred individual items were listed in the guide to the exhibition, and these ranged from topics in basic research to actual demonstrations of weapons. It is not possible to give here an overall description. Instead, very brief accounts will be given of some current researches in a few important fields of general scientific interest.

Hypersonic Aerodynamic Flow

Laboratory investigations of the hypersonic flow of air past a body are very much more difficult than those of supersonic flow. Not only is it difficult to achieve the true stagnation temperatures at the correct Mach and Reynolds numbers of the flow, but also the entire physical picture is now considerably complicated by the occurrence of so-called real gas effects, such as dissociation, ionization and relaxation. The transition from the supersonic to the hypersonic régime occurs at a Mach number of about 5, but all the characteristic features of the latter régime may only become well developed at a much higher Mach number of, say, 15. The development at the Establishment of the light-gas gun-tunnel is an attempt to obtain a satisfactory laboratory facility for use in these investigations. A light gas at high pressure drives a light piston down a sealed gun barrel, and thereby gas (typically air) in front of the piston is compressed and is shock-heated. On completion of sufficient compression in the driven gas, this gas (now hot) is automatically released through a throat, to give expanded flow at Mach numbers between 8 and 15 in the working-section of the tunnel. The running-time in the working-section is about 50 ms. Schlieren photographs are taken, and total force, pressure and heat-transfer measurements are made of the gas-flow past models.

A low-density continuous-flow wind-tunnel with a plasma heater is in operation at the Establishment and is shown in Fig. 1. This facility caters for the simulation of conditions for aerodynamic flow at Mach numbers up to 12 and at altitudes up to 50 miles. Another facility is a small shock-tube in which shocks, travelling initially at Mach numbers of the order of 150, are set up by magneto–gas dynamic impulses.

Thermal Properties of High Explosives

Aerodynamic heating in high-speed flight may result in explosive components acquiring tempera-

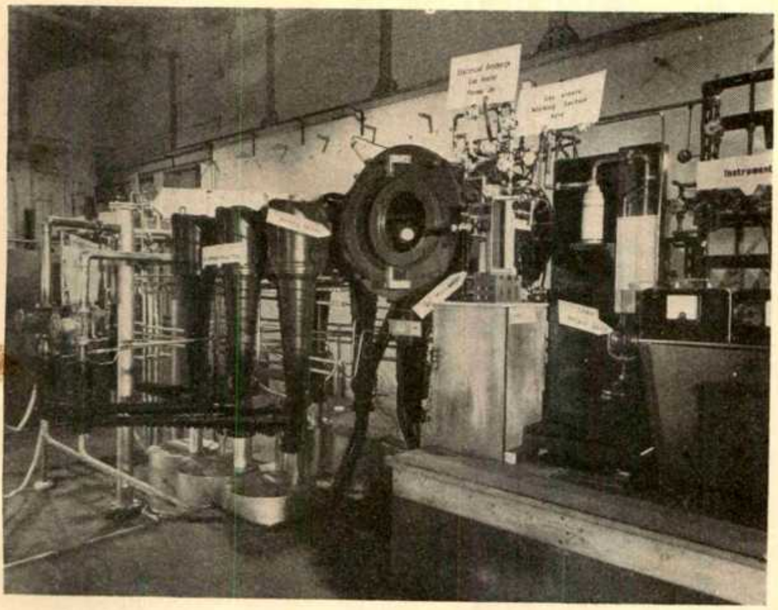

Fig. 1. Low-density continuous-flow wind-tunnel

tures above normal. In order to examine the functioning and safety of these components under these conditions, the physical and chemical properties of high explosives are being investigated at elevated temperatures. These investigations include studies of thermal decomposition, thermal conductivity and sensitiveness.

Thermal decomposition of high explosives is investigated by the measurement of the rate of evolution of gas. This technique has been used particularly for RDX (cyclo-trimethylene trinitramine) and TNT mixtures. The main reaction is the first-order decomposition of RDX in solution in TNT. When RDX is suspended in a saturated solution of RDX in TNT, however, an additional reaction occurs in which it is believed that the TNT decomposes on the surface of the suspended RDX. The heat evolved during the decomposition of high explosives is determined by the rise in temperature of a copper canister, containing the explosive, placed in an electrical furnace the temperature of which is high enough to cause decomposition. In the case of tetryl (2 : 4 : 6-trinitrophenyl methyl nitramine) and TNT, the heat of decomposition is evolved in two stages, indicating the existence of a stable intermediate.

Thermal conductivity is determined by means of an apparatus in which use is made of Callendar's method. The examination of RDX/TNT 60/40 below the melting point of TNT shows that the thermal conductivity decreases with temperature rise.

Impact sensitiveness of a high explosive shows no variation with temperature if this is below its melting point. Above the melting point, sensitiveness depends upon the confinement of the sample. This is illustrated by the results obtained from tests made on small samples of molten high explosive placed upon an anvil. On impact, if the sample is ejected from the surface of the anvil, then the apparent sensitiveness is decreased, as compared with that of the solid high explosive ; but when the sample is confined within a recess in the surface of the anvil, the reverse is the case.

Metallurgy

In the field of ferrous metallurgy, very high strength Si-Cu-Mo-V steels have been developed by the application of research into the effects of various alloying elements on volume changes at transformation temperatures, on martensitic breakdown during tempering, and on hardenability. These steels have tensile strengths greater than 140 tons/in.^{2}, good ductility and impact resistance, and are very resistant to tempering. The suitability of these steels for various potential applications is being evaluated ; these applications include vehicle springs and torsion bars, aircraft high-tensile steel forgings and castings, missile components fabricated from sheet, and cold extrusion tools.

Research on materials at high temperatures has enabled considerable progress to be made in producing high-quality arc-melted molybdenum alloys and in working these alloys to bar, rod and sheet by means of forging, swaging, extrusion and rolling processes. The ductile–brittle impact transition temperature has been lowered to 225° C. by a metal-working process, but by using electron-bombardment melting for zone-refining, this temperature has been further substantially lowered to −140° C. in purified single crystals and to −80° C. in purified polycrystals. Progress is also being made in the protection of molybdenum at high temperatures, and promising results are being obtained with multi-layers of electro-deposited coatings in combination with ceramic.

The occurrence of repeated high stresses in certain engineering structures has necessitated design for a limited life. In this connexion, a push–pull machine has been developed for high-strain fatigue testing that is capable of producing failures in specimens down to within a single cycle.

Plasma-jet and transferred arc torches have been developed, and their use for the spraying of high melting-point metals as well as ceramics and other refractory materials is receiving considerable attention.

Ultra-high Speed Radiography

In certain armament investigations, the presence of high-luminosity, smoke and flying debris precludes the use of high-speed photographic techniques for observing events. Radiographic techniques must then be used instead. Techniques are now available for taking single-shot radiographs through approximately 2 in. of aluminium, with exposure times of less than 1 μsec. Some current research is concerned with the development of megavoltage systems which make it possible to penetrate 3 in. of steel, with the same exposure time. These techniques have proved useful in a wide range of explosion studies and have also been used in studies of industrial processes such as the flow of molten steel into moulds of complicated shape.

Other work involves the use of the Establishment's 5-MeV. linear-accelerator X-ray generator. This

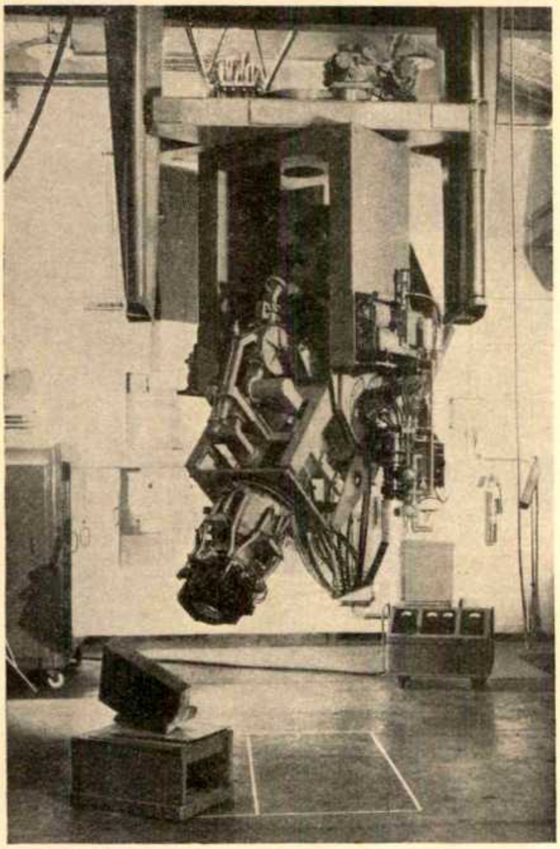

Fig. 2. 5-MeV. linear electron accelerator for radiography. (Penetration, 14 in. of steel; output, 600 röntgens/min. at 1 m.)

equipment (Fig. 2), although primarily used for the radiographic examination of heavy sections (up to 14 in. of steel, with a wire-sensitivity of 0·5 per cent), has also been used in strobo-radiographic work. The generator is operated with a pulse of 1·8 μsec. duration at a maximum frequency of 500 c./s. In this way, studies have been made possible of the valve and cam movements in a single-cylinder internal combustion engine operating at 1,800 r.p.m. Another application made of the technique is to the study of the response of enclosed systems to vibration.

Mechanics of Solids

The propagation of stress waves in solids and the mechanical properties of materials under dynamic conditions are subjects of fundamental importance in connexion with the investigation of certain problems of explosion or impact loading. Theoretical and experimental research is being done in this subject for various materials, including metals and visco-elastic solids such as brittle plastics and other high polymers. Of particular interest is the application of modifications of the Hopkinson pressure-bar technique to compression tests of softer metals and visco-elastic solids. In this type of mechanical test, a short cylindrical specimen is inserted in a 'split' pressure-bar. At one end of the pressure-bar, a stress pulse is generated by the detonation of a small explosive charge. Measurement of the change in time of the displacement produced at the other end of the pressure-bar enables stress–strain characteristics of the specimen to be derived for durations of applied loading of 10–50 μsec. The test has proved particularly useful in the study of visco-elastic solids. The dynamic value of Young's modulus that is derived in this way is in good agreement with values obtained from vibration and stress-wave propagation studies. For the softer metals, it is found that whereas the initial flow stress is significantly greater than that observed at low strain-rates, further deformation at these ultra-high strain-rates appears to be accompanied by unsuspected effects which are being further investigated. Considerable plastic flow in these materials occurs during the fall in stress, and in some cases at sufficiently large strain the dynamic stress–strain curve appears to fall below the static one.

Computational Techniques

A Ferranti Mark I* high-speed electronic digital computer, *Amos*, is used extensively to obtain numerical solutions to mathematical problems arising in the course of studies in a wide variety of scientific and engineering fields. Some examples are the mechanics of fluids and solids and the analysis of individual (and also systems of) weapons.

One particularly interesting recent development is a new computational technique for the numerical integration of systems of non-linear wave-propagation equations in three independent variables. The integration is made along bi-characteristic curves of the equations. Partial differential equations of this (or equivalent) type are of common occurrence in mathematical-physical investigations and methods of solving them are therefore extremely important. Examples occur in the theory of supersonic flow of fluids and also in theories of plastic flow in metals and other solids. So far, the technique has been applied only to the investigation of the steady supersonic aerodynamic flow around a body with the shape of a delta-wing. The theoretical predictions of pressure distributions agree very well with experimental results obtained in wind-tunnel tests. In principle, the technique could be extended to include equations of similar type but in four independent variables, but the computational work would then be severely increased.

Amos has also been used to make important advances in the design of lens optical systems. The important optical aberrations cannot all be reduced to satisfactory minima if the system contains only a few elements, and the consequent need for complex systems introduces difficult problems of design. The recent development of a new and efficient technique of optimization has made possible the reduction of these aberrations to several orders below that previously achieved.

In each of the above investigations a new analytical approach has provided the basis of the computational technique, but it is interesting to note that the use of the technique was possible only with the aid of the computer.

For certain types of numerical problems formerly solved on desk computing machines, it has been shown that the use of the full code of general purpose computers may often be advantageously avoided, particularly with less experienced programmers in mind. A simplified code, 'Intercode', has been developed for use on *Amos*, and several highly successful applications have been made of this procedure.

GENERATION OF TEMPERATURES BELOW 1° K.

On December 11, 1959, the Physical Society Low-Temperature Group held a symposium at the Institute of Physics on "Generation of Temperatures Below 1° K.", with Dr. P. H. Sykes as chairman. As on previous occasions, the programme was arranged to give plenty of time for questions and discussion. Very little unpublished work was presented, the purpose being chiefly to give an account of established principles and techniques to members of the Low-Temperature Group interested in this field. A detailed report of the proceedings is to be given elsewhere; the following is a brief outline of the material presented.

Following the chairman's introductory remarks, Mr. G. Davey (Clarendon Laboratory, Oxford) discussed the use of liquid helium-4 as a constant-temperature bath down to about 0·74° K., which is effectively the lower limit since the vapour pressure is very small there and is decreasing rapidly with temperature. If only a small pumping speed is to be used, the evaporation rate and hence heat influx to the bath must be drastically reduced, which entails the use of a narrow constriction in the pumping tube just above the bath, to avoid excessive heat influx through the superfluid film. Alternatively, to avoid a constriction, and allow a larger heat influx, a very large pumping speed must be used. Mr. Davey described an apparatus based on this principle, which used a pumping speed of 900 l./sec. and reached a temperature of 0·74° K. For comparison, a temperature of 0·75° K. can be obtained with a speed of 10 l./sec., and a suitably small constriction. The choice of method depends on the type of experiment and the equipment available.

The lower limit of constant-temperature baths can be extended to nearly 0·3° K. by use of the light isotope helium-3, owing to its much higher vapour pressure. Mr. M. Hobden (lately of the Clarendon Laboratory, now at the Royal Radar Establishment, Malvern) summarized the properties of ^{3}He relevant to this purpose, and described several ^{3}He cryostats, which, because of the scarcity of the substance, have come into use only in the past few years. In the 'single-shot' type, ^{3}He is first condensed into the cryostat and the vapour then pumped off to reduce the temperature. An alternative arrangement is the circulating type, wherein the gas is condensed in a vessel immersed in a helium-4 bath, and the liquid allowed to drip (through a needle valve or other high resistance) into the experimental space, where it evaporates and is pumped off, then compressed and re-condensed to continue the cycle. The latter method is more complicated but needs less ^{3}He, and can deal with a larger heat influx. There are no difficulties associated with a superfluid film in ^{3}He, but it must be carefully purified (notably of tritium and ^{4}He) and needs a fairly elaborate gas-handling system. On the whole, the cryostats are simple and convenient, and will undoubtedly come into increasing use.

Dr. E. Mendoza (University of Manchester) gave an outline of the principles and techniques of the adiabatic demagnetization method, whereby paramagnetic salts may be cooled to about 10^{-3} ° K., and other substances, through them, to about 10^{-2} ° K. The entropy of a paramagnetic salt may be reduced by applying a magnetic field, or by decreasing the temperature. The basic principle is therefore to magnetize the salt isothermally, lowering its entropy, and then to remove the magnetizing field isentropically, when its temperature must drop. The final temperature is proportional, ideally, to the ratio of the initial temperature to magnetizing field, typical starting conditions being 1° K. and 10^4 gauss. In practice, the final temperature is limited by the interactions between the ions, which may be reduced by using a magnetically dilute salt. Temperatures are measured by various methods, most commonly by determining the susceptibility of the salt, which is related to the temperature in the ideal case through Curie's Law. The absolute-temperature scale is established by experiments involving Carnot cycles. The cold salt will warm up at a rate determined by its specific heat and the heat influx, and one of the difficulties is frequently found to be the reduction of unwanted heat influxes due, for example, to mechanical vibrations or to desorption of exchange gas as the salt warms up. Dr. Mendoza also discussed means of obtaining isothermal conditions in the demagnetization region, for example, by isothermal demagnetization or by use of the magnetic refrigerator. Another problem encountered is the design of 'heat switches' to make and break thermal contact, among which are the superconducting, 'bath plug', and ^{3}He rectifier types. In the discussion, Dr. K. Mendelssohn (Clarendon Laboratory) mentioned the use of adiabatic magnetization of a superconductor for obtaining temperatures of a few tenths of a degree.

The more esoteric technique of nuclear adiabatic demagnetization was described by Dr. N. Kurti (Clarendon Laboratory). Since the limiting temperature in the demagnetization method is determined by the magnetic interactions present, much lower temperatures can be reached by reducing these, namely, by choosing a substance the entropy of which at low temperatures is determined not by the electron spins but by the nuclear spins, which have magnetic moments smaller by a factor of about 10^3. To obtain the same entropy reduction as in the electron spin case, it is necessary to use a ratio of magnetic field to initial temperature about 10^3 times larger. In one experiment, for example, a specimen of copper was demagnetized from 0·012° K. with a field of 30 k. gauss, the low starting temperature being achieved by 'ordinary' demagnetization of chrome potassium alum. Dr. Kurti explained some of the problems of technique, and of interpretation of results, emphasizing that the lowest temperature reached, about 10^{-6} ° K., was that of the nuclear-spin system, not of the lattice or the conduction electrons. To obtain cooling of the bulk material, it would be necessary to insert a heat switch between the electronic and nuclear stages. Even without this, it should be possible to cool, and do experiments on, the conduction electrons down to at least 10^{-3} ° K

Dr. H. London (Atomic Energy Research Establishment, Harwell), in a paper entitled "More Abstruse Techniques", analysed the possibility of using the reversible adiabatic dilution of liquid ^{3}He with liquid ^{4}He. Such a dilution, in analogy with the adiabatic expansion of a perfect gas, leads to a cooling which is enhanced by the latent heat of mixing. A complete analysis of the method is not simple, and the possibilities may be limited by the presence of the phase separation region in liquid ^{3}He–^{4}He mixtures. In practice, reversible dilution can be achieved by introducing superfluid ^{4}He through a superleak into pure liquid ^{3}He, or into a ^{3}He–^{4}He mixture. One might expect to work with temperatures around 0·1° K.—perhaps even lower—although no direct experiments have been carried out at this stage. An advantage of the method would be that it does not require the use of magnetic fields, on the other hand, if it were to be used as a continuous refrigerator the system would be quite a complicated one.

The symposium ended with a description by Dr. D. F. Brewer (Clarendon Laboratory) of two recent sets of experiments on helium-3 carried out at the Ohio State University, using the adiabatic demagnetization method for cooling. Down to 0·085° K. the specific heat of the liquid was found to have no anomaly such as occurs with liquid helium-4, and appears to vary linearly with temperature below about 0·1° K. In this respect the liquid behaves like a Fermi–Dirac gas with effective mass twice that of a ^{3}He atom. In other respects, such as its increase of specific heat with pressure below 0·16° K. and its negative expansion coefficient, it is unlike a perfect Fermi-Dirac gas. These results can be explained theoretically. Experiments on the melting curve confirm by direct measurement the presence of a minimum at 0·32° K. which had already been inferred from other experimental and theoretical sources. The region of the melting curve below the minimum is inaccessible to measurement by the usual methods, and hence evaded observation for some time; the measurements described were carried out by use of a strain gauge as pressure transducer, which circumvents this difficulty. They confirm the existence in solid helium-3 at low temperatures of forces additional to the magnetic spin-spin interaction.

D. F. Brewer

FOOD RESTRICTION AND SALT PREFERENCE IN RATS

By HANS KAUNITZ, LESTER M. GELLER, CHARLES A. SLANETZ and RUTH E. JOHNSON

Department of Pathology, Institute of Comparative Medicine, and the Division of Neuropathology, College of Physicians and Surgeons, Columbia University, New York

MOST human beings, as well as many other animals, will consume an appreciably greater amount of salt, if it is available, than is required for survival, growth or reproduction. The possible relationship between heavy salt intake and hypertension has been recently re-emphasized[1], while the beneficial effects of high salt intake in such conditions as profuse sweating[2], and in adrenal[3] and certain cases of renal[4] insufficiency are well known. It has been suggested that the salutary action of salt in these cases may not be due to a simple replacement phenomenon, but rather to the consequences of a stimulating action of sodium chloride upon certain body tissues[5]. Presumably such an enhancing effect of salt might also influence certain behavioural responses of the organism to its environment.

The preference of rats for solutions of sodium chloride, particularly in isotonic concentration, as against water, has been well established[6–9]. Our interest in this area lay in investigating possible differences in the level of fluid intake of rats drinking salt solution, as compared with fresh-water drinkers, under conditions of marked and moderate food restriction, and also in studying the possible effects of excessive salt intake upon survival, growth (body-weight), reproduction, and weights of certain organs. Studies of the speed of eating and maze activity of drinkers of salt solution will be reported later.

Male rats from our stock colony (Columbia–Sherman strain, arbitrarily bred as a closed colony for at least fifteen generations) were maintained from weaning (24 days of age) on a purified diet[10] consisting of 30 per cent alcohol-washed casein, 20 per cent lard, 44 per cent dextrose, 2 per cent cellulose, 0·5 per cent calcium carbonate, and liberal amounts of all known vitamins. To this diet was added 4 per cent of U.S. Pharmacopeia salt mixture XIII, containing enough sodium chloride to allow a level of approximately 0·15 per cent of the last named in the final diet. This quantity of salt had been found to be adequate for permitting maximal growth, survival and reproduction in our rat colony, and it was our intention in these experiments to avoid any limiting factors in the diet *per se* which might interfere with such functions.

Each animal was housed in a roomy cage, on wood shavings. The cages were supplied with water bottles bearing machined stems which minimized dripping sufficiently to permit reliable determinations of liquid intake to be made by weighing the bottles to an accuracy of ± 1 gm. All young were earmarked. and then weighed at 28, and again at 35, days of age. Two matching groups of forty rats each were formed having identical average weights at 28 and again at 35 days of age, a procedure which strongly implied similar average growth-potentials in both groups. One group continued to drink water, and the other was offered a bottle of 1 per cent salt solution and one of water.

Shortly thereafter an attempt was made to equate the groups with respect to temperamental or personality characteristics. Each rat was placed in a Lashley III maze (eight *culs de sac*)[11], and observed

Table 1. AVERAGE DAILY FLUID INTAKE OF RATS DRINKING 1 PER CENT SALT SOLUTION AND WATER, OR WATER ALONE, UNDER DIFFERENT CONDITIONS OF AVAILABILITY OF FOOD

Group	No. of rats	Age* (days)	Weight* (gm.)	Average daily fluid intake (c.c)								
				Free access to food (14 days)			Weight reduction (7 days)			Maintenance of reduced weight (21 days)		
				Water	1 per cent salt	Total	Water	1 per cent salt	Total	Water	1 per cent salt	Total
Salt solution and water	20	282	471 ± 18†	7 ± 1·2	34 ± 3·6	41 ± 3·1	6 ± 0·8	59 ± 5·7	65 ± 5·5	5 ± 0·8	65 ± 5·5	70 ± 5·7
Water only	20	282	459 ± 21	25 ± 1·2	—	25 ± 1·2	23 ± 2·3	—	23 ± 2·3	25 ± 1·6	—	25 ± 1·6

* Age and mean weight of animals at beginning of fluid intake determinations (day 1 of period of free access to food)
† Standard error of the mean.

for 5 min. on each of four consecutive days. As possible indicators of the nature of the response of each animal to a novel situation, the time required to leave the starting box, the number of alleys investigated, and the distance traversed toward the goal box, as well as the number and consistency of boluses dropped—an 'emotional' indicator to some workers[11]—were recorded. From the originally matched groups of forty rats each, two sub-groups of twenty were selected on the basis of the similarity of their behaviour in the maze. The final groups, therefore, consisted of twenty animals each, well matched as to age and growth tendency, and perhaps to a lesser degree, as to certain temperamental or personality characteristics.

Approximately eight months later, measurements of liquid intake under different conditions of availability of food were begun. The average daily liquid intake of the salt and water groups was determined over a 2-week period, with food freely available. Both groups consumed approximately 12–14 gm. of food daily during this time. Thereafter the animals were placed on a deprivation schedule designed to reduce their weight and then maintain it at the lowered level. To accomplish this, 5 gm. of food were given each animal daily for 4 days. During the next three days they received only enough food (1–8 gm.) to reduce their weight to 85 per cent of the weight at the beginning of the determinations[13]. During the next three weeks the weight of all rats was kept constant, within a daily average fluctuation of ± 2 gm. per group, by supplying them with an average ration of 9 gm. per day. Determinations of liquid intake during the periods of weight reduction and maintenance were made. Thereafter the animals were given food *ad libitum* and later used for other studies.

As seen from Table 1, the average daily fluid intake of the group drinking only water remained almost constant during the three different periods of food availability. The salt group behaved differently. As expected, these animals, when offered a choice between tap water and a 1 per cent salt solution, strongly preferred the latter under all conditions. Their fluid intake under ordinary conditions, that is, with food freely available, was significantly higher than that of the water group ($t = 4·82$; $P < 0·001$). During both periods of food restriction the average daily intake of fresh water in the salt group did not vary significantly from the volume consumed during the period of free access to food. The consumption of 1 per cent salt solution, however, rose markedly, so that the average number of c.c. drunk daily during the seven days of weight reduction and the fourteen days of maintenance of reduced weight was almost twice that consumed under ordinary cage conditions.

Thus the results are clear in indicating that when rats are deprived of their normal ration of food their consumption of water does not change, but when given the opportunity, their consumption of a 1 per cent salt solution will rise steeply, so that their average daily total fluid intake is almost three times (Table 1) that of animals drinking water only.

The average daily food ration necessary to maintain the animals at the desired level of weight reduction (85 per cent of initial weight) varied from 8·6 ± 0·3 to 10·4 ± 0·4 gm., with a mean ration, as mentioned earlier, of 9 gm. in both the experimental and control groups. This suggests that the increased intake and excretion of salt and water were carried out efficiently by the salt solution drinkers, since additional food or caloric intake was not required by this group.

After one year of observation, no significant difference between salt and water drinkers was noted in survival, growth (gain in weight), or fertility (Table 2). A separate group of twenty female rats, maintained on a free choice of 1 per cent salt solution and/or water for one year, but not included in any of the other studies, proved also to be fertile. Litters from male and female salt drinkers, each mated with a fresh-water drinker of the opposite sex, were fully the equivalent of control progeny in number, survival, and weight at weaning. It is not impossible, however, that differences in survival and fertility between salt and water drinkers would have become apparent had the observation period been carried beyond one year.

Determinations of the weights of heart ventricles and kidneys after food deprivation were made on two additional series of rats, not included in the fluid intake studies. To provide a background of organ-weights in our rat colony against which to evaluate these findings, the organ-weights of 427 normal animals, ranging in weight from 60 to 700 gm. were determined. A log–log plot of organ versus body-weight gives a positive straight-line relationship between the two over wide ranges of body-weight, with a uniform spread (standard deviation) about

Table 2 WEIGHT, SURVIVAL AND FERTILITY OF MALE RATS OFFERED A 1 PER CENT SALT SOLUTION AND WATER, OR WATER ALONE, AFTER ONE YEAR OF OBSERVATION

Group	No. of rats	Average weight (gm.) ±standard error	No. alive		No fertile
Salt solution and water	36	491±22	26	$\chi^2 = 2·432$ df = 1 $P > 0·10$	26
Water only	32	486±17	28		28

These groups are not identical with the animals used in the fluid intake studies, since a number of those were killed for other determinations. Comparable male animals, selected and maintained in the same way as were the fluid intake groups, but not subjected to the deprivation schedules, have been included instead.

Table 3. Analysis of the Effect of Food Restriction upon Heart and Kidney Weights in Rats Drinking 1 per cent Salt Solution and Water, or Water only

Group	No. of rats	Average weight at death (gm.)	Average weight of heart ventricles (gm.)		Average weight of both kidneys (gm.)	
Salt solution and water	30	293 ± 4·8*	0·73 ± 0·014	$t = 4·49$ $P < 0·001$	1·9 ± 0·05	$t = 3·12$ $P < 0·002$
Water only	30	291 ± 4·7	0·65 ± 0·011		1·7 ± 0·04	

The six groups of ten rats each, seen in Fig. 1, have been re-grouped into two series of thirty each for computational purposes. Animals were killed at end of period of maintenance of reduced weight, at 124 days of age.

* Standard error of the mean.

each mean weight[14]. In Fig. 1, the solid lines represent the normal relationships of heart ventricle and kidney weights to body-weights, over the body-weight range of the animals in the current experimental series. The dotted lines represent the standard deviations of the plotted mean organ weights.

Experimental results are presented in Fig. 1 as points, each of which represents the mean organ weight of ten animals, killed directly after termination of the period of maintenance of reduced weight, at 124 days of age. The salt animals were offered a choice of 1 per cent salt solution or water from weaning (24 days), while the others received water only. It can be seen that the effect of food restriction was to reduce the average weights of ventricles and kidneys of both salt and water drinkers, as compared with colony control results, but the degree of weight loss of both organs was significantly less in the salt solution group than in the straight water drinkers (Table 3). A second series (not shown in Fig. 3) of 50 salt solution drinkers and 53 water-drinking rats was kept on the food deprivation and maintenance of reduced weight schedule already described, and then permitted to eat freely for 3–16 weeks thereafter. No deviations of their ventricle and kidney weights from those of the colony controls were found. Both groups ranged, in age, from 84 to 455 days, and in average weight from 310 to 512 gm., at the time they were killed for determination of organ weights.

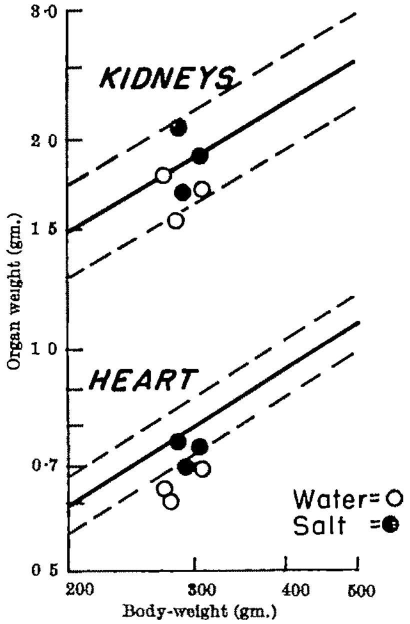

Fig. 1. Effect of food restriction on weight of heart ventricles and kidneys in rats drinking 1 per cent salt solution and water, or water only. Each point represents the average organ-weight of 10 animals. The solid lines are log–log plots of organ- vs. body-weights of normally reared animals; the broken lines represent the standard deviations of these plots

No differences in the weights of the adrenal glands, livers or thymus glands were noted between the salt drinkers and the rats drinking water. Under food restriction the weight of the adrenals increased by about 20 per cent in both groups, and that of the liver and thymus gland decreased by 30 and 50 per cent, respectively. In the groups that were given free access to food for 3–16 weeks following reduced food intake, the weights of these organs closely paralleled normal values.

Taken together these results document certain consequences (or the lack thereof) of freely chosen, long-term ingestion of salt. Consumption of 1 per cent salt solution for periods of more than a year had no effect upon the weight of the heart ventricles or kidneys of normally reared rats. Under conditions of food restriction the loss of weight of these organs was significantly reduced in the presence of salt intake. Survival and body-weight were not affected after one year of drinking 1 per cent salt solution, nor was the fertility or the quality or number of offspring of such animals altered.

During the period of reduced weight maintenance the salt and water groups both required the same amount of food to maintain their weights. Yet the animals given a free choice of 1 per cent salt solution or tap water increased their average daily fluid intake (consisting overwhelmingly of 1 per cent salt solution and *not* water) to 25 per cent of their body-weight (Table 1), while the intake of the water group remained stable.

We believe these results provide an example of rapid learning in the rat, where a lack (food deprivation) in one aspect of consummatory behaviour (eating) leads to a marked change (increased intake of salt solution) in another consummatory response (drinking), in the presence of adequate neural equipment, and experience (rapidly acquired preference for 1 per cent salt solution). The rat's preference for 1 per cent salt solution is manifested quickly, and is maintained consistently under normal cage conditions. (We do not believe it was necessary to give the animals a free choice of salt solution or water from the time of weaning in order to demonstrate these findings. The long-term intake of salt solution was permitted only for the purposes of the toxicity studies.) When the amount of food available to the rat was curtailed, its intake of another appetitively stimulating substance, salt, increased, but only to a certain level. These animals were not starving, and presumably the maximal satiating effect of salt solution was reached at that level.

This interpretation is supported by the results in Table 1, which indicate that during the 7-day period of weight reduction, the average daily intake of salt solution was 59 c.c.; but during the next 21 days of maintenance of reduced weight, when the animals actually were receiving a greater amount of food than before, though still less than under *ad libitum* feeding, the intake of salt solution became stabilized at 65 c.c. Thus the consumption of salt solution was approximately the same under both conditions of food reduction, but with ample food available, it was markedly lower (34 c.c. a day). That this effect is transitory and related to the availability of food was further shown by observation of the rats after their return to *ad libitum* feeding, when their average intake of salt solution dropped to initial levels.

Hebb has presented a theoretical account of the role of learning in hunger, eating, and the cessation of eating[15]. He illustrates some of his points with the salted nuts phenomenon, where once they are tasted, it becomes increasingly difficult to let them alone. Hunger has increased, but how? As Hebb says, ". . . a lack of food cannot be increased by eating something, and stomach contractions are stopped by chewing and swallowing" (ref. 15, p. 200). Nor is it feasible to believe that a taste of salted nuts increases appetite and not hunger, for as Hebb points out, the distinction between the two, at least in terms of an understanding of the physiological control of eating, is highly artificial. If, however, one considers hunger, ". . . to be neither a particular condition of the body, nor a set of sensations from the stomach, but an organized neural activity that can be aroused (like any other conceptual process) in several ways . . ." (ref. 15, p. 203), the role of salt as a provocative agent in consummatory activity is somewhat clarified. Drinking only tap water evidently did not provide an associative link for the animals, in these experiments, between the consummatory response made and appetite. Put another way, it did not serve (as did salt) to arouse a pattern of learned behaviour associated with appetite and/or hunger.

The recognition of the role of learning or experience in activities generally viewed as responses to internal needs, or primary biological drives, will require a re-appraisal of current ideas about hunger and thirst, and perhaps of greater significance for behaviour theory, of the concept of motivation, in general. The increasing recognition that the functional division of the nervous system into 'central' and 'peripheral' (or 'sensory') mechanisms is probably unwarranted with regard to behaviour should be of particular pertinence in this connexion[16]. Recent work by a number of investigators[17-19], as well as a current review[20] and a book[21], emphasizing the role of experience in the determination of patterns of consummatory behaviour, lend additional support to these conclusions.

This work was supported in part by research grant *B*-1620 (awarded to the Division of Neuropathology) from the National Institute of Neurological Diseases and Blindness, U.S. Public Health Service.

NEWS and VIEWS

Radio Research in the D.S.I.R.: Dr. R. L. Smith-Rose, C.B.E.

On September 30, Dr. R. L. Smith-Rose will retire as director of radio research in the Department of Scientific and Industrial Research. Dr. Smith-Rose has been associated with the work of the Radio Research Board of the Department since the formation of the Board in 1920. In 1919 he joined the scientific staff of the National Physical Laboratory as a member of the Electricity Department, and a few years later, when the new 'Wireless Division' of the Department was formed, Smith-Rose was appointed scientific officer-in-charge. This was the nucleus of the Radio Division of which he became superintendent in 1939. In 1948 he was appointed to the new post of director of radio research in the Department of Scientific and Industrial Research, with headquarters at the Radio Research Station, Slough. This Research Station is now known internationally for its work in the fields of radio wave propagation, tropospheric and ionospheric research, radio atmospheric noise, radio standards and measurements and, more recently, for observations and predictions on artificial Earth satellites. Smith-Rose's personal research activities have included fundamental and pioneering investigations in radio direction finding, studies on the electrical properties of soil and sea water, and on the propagation of radio waves over the ground and in the troposphere. He has always been very active in national and international radio organizations and has held numerous posts of distinction. He was chairman of the Radio Section of the Institution of Electrical Engineers in 1943, and has been awarded premiums on five occasions for original papers read before the Institution. He is a Fellow and former vice-president of the Institute of Radio Engineers (New York) and is an honorary member of the Institution of Radio Engineers, Australia. He is a vice-president of the International Scientific Radio Union. In 1947, Dr. Smith-Rose was awarded the U.S. Medal of Freedom with Silver Palm for his service in scientific research and development, and for co-operation with American scientists. He was made C.B.E. in 1952.

Mr. J. A. Ratcliffe, C.B.E., F.R.S.

MR. J. A. RATCLIFFE has been appointed to succeed Dr. Smith-Rose. At present Mr. Ratcliffe is reader in physics in the University of Cambridge and head of the Radio Section at the Cavendish Laboratory. He entered Cambridge in 1921 with an open scholarship to Sidney Sussex College and first joined the Cavendish research group in 1924, working with Appleton in some of his earliest investigations of the ionosphere. In 1927 he was appointed demonstrator at the Cavendish Laboratory and in the same year elected a Fellow of Sidney Sussex. During the War, Ratcliffe was employed on various aspects of research and development in radio, mainly at the Telecommunications Research Establishment, Malvern. For a year he was seconded to the Army to start the radar school at Petersham and later returned to the establishment to undertake responsibility for establishing and running the Post-Design Service organization which was concerned with performance problems of radar equipment under service conditions. In 1947 he was made O.B.E., for this war-time work, and in 1959 C.B.E., for advisory work to the Ministry of Supply. In 1951 he was elected a Fellow of the Royal Society, and at the present time he is president of the Physical Society, vice-chairman of the Electronics and Communications Section of the Institution of Electrical Engineering, and overseas vice-president of the Institute of Radio Engineers (New York). Apart from the war years, Ratcliffe's work has been carried out at Cambridge where he has built up a major radio research school. Over a period of thirty-five years he has made extensive researches on the propagation of radio waves and on the ionosphere.

U.K. Atomic Energy Authority : Mr. H. Cartwright, M.B.E.

MR. H. CARTWRIGHT, at present serving as deputy director of industrial power in the Development and Engineering Group of the United Kingdom Atomic Energy Authority at Risley, has been appointed director of industrial power. Mr. Cartwright was born in 1919 in Manchester. He was educated at William Hulme Grammar School, Manchester, and at St. John's College, Cambridge, where he took a first-class honours degree in the Mechanical Sciences Tripos in 1940. During the period 1942–46 he was a signals officer on ground radar stations in the Royal Air Force, reaching the rank of flight lieutenant. After working for the Decca Navigator Co., Ltd., Brixton, and the English Electric Co., Ltd., Stafford, he joined the Atomic Energy Division of the Ministry of Supply at Risley in 1949 as a design engineer. In 1954, on the formation of the Atomic Energy Authority, Mr. Cartwright became an assistant chief engineer in the Authority's Industrial Group at Risley. He was promoted to chief engineer in 1955, assistant director in 1956 and deputy director of industrial power in 1958.

International Atomic Energy Agency: Research Grant

THE first research grant under the Exchange and Training Programme of the International Atomic Energy Agency has been awarded to Dr R. P Agarwala. Dr. Agarwala has graduated from the Agra College, India, and the Imperial College of Science and Technology in London; he has published a number of papers on metallurgy Dr. Agarwala will undertake a year of research in the field of solid-state physics and chemistry at the Massachusetts Institute of Technology. These research grants are awarded mainly to scientists with considerable research experience, who are already working in their own countries on a promising line of research which cannot be developed fully there because of lack of equipment or laboratory facilities.

Silver Jubilee of *Science and Culture*

THE Silver Jubilee issue of *Science and Culture* (25, 1), organ of the Indian Science News Association, is one of which its sponsors may justly be proud. Besides a brief and modest history of the Association itself, there is an account of the rise of scientific research in India with tributes to those pioneers who did so much in difficult times. Among the contributors to the Silver Jubilee edition are distinguished men of science from various parts of the world. Hans von Euler, of the University of Stockholm, examines experimental work on nuclear acids and nucleotides, and A. I. Oparin, of the Moscow Academy of Sciences, discusses the origin and development of life on Earth. J. D. Bernal considers priorities and phasing in the use of science, while Ivan Matels, of the Czechoslovak Academy of Science, describes research and production of antibiotics in Czechoslovakia. There are also a number of articles by eminent men of science from India. The journal is published monthly from 92 Achanya Prafullachandra Road, Calcutta 9, at an annual subscription rate of £1.

Alcohol and Road Safety

ALTHOUGH the problem of alcohol and road safety has been much in the public eye, there has hitherto been little precise evidence as to the effects of small quantities of alcohol on driving skill. For this reason, the careful study by Prof. George Drew and his colleagues recently published by the Medical Research Council ("Effect of Small Doses of Alcohol on a Skill Resembling Driving", by G. C. Drew, W. P. Colquhoun and Hazel A. Long M.R.C. Memorandum No. 38. H.M.S.O. 7*s*. 6*d*. net) will attract widespread interest. This report describes the effects of small doses of alcohol (the highest being roughly equivalent to only five fluid ounces of whisky for a man of average weight) upon performance on the 'Miles motor driving trainer'—a complicated tracking task which has a good deal in common with actual driving. It was found that the mean error of forty subjects on the test increased significantly with increasing blood alcohol, the shape of the curve being strikingly similar to the blood and urine alcohol curves On the other hand, the average speed of 'driving' showed no significant change. Marked differences between subjects were however observed, and the authors rightly place weight on temperamental factors as governing individual reactions to alcohol.

These results strongly suggest that amounts of alcohol far too small to give rise to recognizable signs of intoxication may none the less significantly impair driving ability. At the same time, the authors are properly cautious in generalizing from their findings to driving—and drinking—under conditions less austere than those of the laboratory. The effects of small doses of alcohol upon confidence, decision and judgment were assessed little, if at all, in the present series of experiments, and the range and extent of compensatory activities have still to be defined with precision. None the less, this report deserves the most careful attention on the part of all concerned with the pressing problem of road safety.

Domestic Oil-heating

"BRITAIN Turns to Oil Heat" is the title of an anonymous but significant contribution to the combined summer and autumn (1959) number of the *Esso Magazine*, house organ of the Esso Petroleum Co. Domestic heating by oil is increasing rapidly. Just after the War there were 5,000 houses with oil-fired central heating; in 1957 there were 16,000; and in 1958, 40,000. Similarly, portable oil heaters have increased in popularity from 2½ million to more than 10 million in the past five years Perhaps the most interesting information in this article, especially in view of recent publicity given to fatal accidents with oil heaters, is quoted from a consumer's association. Ten different models were burned together in a room for several hours without creating odour. They were then knocked on their backs to see if they would spill burning oil; but in every case the flame either went out or returned to normal burning when the heater was set up again in correct position. Finally, the models were subjected to blasts of air to see whether flames would burn in a dangerous manner. In no case did anything catch fire, a remarkable result and tribute to the various heater designs involved.

Parametric Amplifier Diode

'EW97/1', a variable capacitance diode designed for use in parametric amplifiers at frequencies up to *S*-band, is now in production by the General Electric Co., Ltd. (Semiconductor Division). The Company claims that it is the first device with these qualities to be made available in the United Kingdom. The price is considerably lower than that of the units which previously had to be imported. The diode is suitable for use in radar and other communications systems. Designed for high power dissipation, it needs no elaborate precautions against surges. It is mounted in a coaxial structure for direct insertion into coaxial and wave-guide circuits and it has the very low series inductance of 0·5 μH. A reverse polarity version ('EW98/1') is also available. Because of its very low forward impedance and very high reverse impedance, the device can be used as a micro-wave switch. Another application is as a frequency multiplier—an important aid towards the future design of micro-wave receivers based entirely on solid-state devices.

Palæolithic Remains at Willendorf

EVERY prehistorian knows of the Venus of Willendorf, and some of them know that the figurine comes from a site near the village of the same name which lies on the left bank of the Danube between Melk and Krems, upstream from Vienna. The figurine itself is made of a fine-grained oolite, is some 10 cm. in height, and is highly conventionalized. It can be dated to a late palæolithic epoch. But up to now very little detail has been generally known about the find, the site itself, and the associated industry. Now three fascicules of the Prehistoric Commission of the Austrian Academy of Science have been devoted to these matters (Mitteilungen der Prähistorischen Kommission der Österreichischen Akademie der Wissenschaften. VIII und IX Band: Willendorf in der Wachau: Monographie der Paläolith-Fundstellen I–VII. 1 Teil: Text. Pp. v+219. 2 Teil: Inventar. Pp. 79. 3 Teil: Abbildungen. Abb. 124. (Wien: Österreichische Akademie der Wissenschaften, 1959)). At Willendorf there are a number of loess sites which have yielded upper palæolithic industries; the famous figurine came from site 2. The first fascicule includes a full account of the sites and the various excavations that have taken place there; Part 2 is a catalogue of all the finds of stone and bone tools that have been unearthed; Part 3 is entirely taken up with pictures of the more important tools, which enable datings for the various levels to be suggested. A work of this nature is long overdue. Now at last prehistorians have the full facts connected with one of the more important works of art of late palæolithic man that has survived.

The Transvaal Museum

THE annual report of the Transvaal Museum, Pretoria, for the year ended March 31, 1959, once again directs attention to the desperate need for more accommodation The Trustees consider that the people of South Africa have been unduly penalized in that large sections of the collections in both the natural sciences and history are steadily deteriorating owing to lack of storage and display space. Proposals for a separate and independent cultural history museum and an open-air historical museum are also being discussed at a high level with the Minister of Education. An entrance charge (1*s*. per head for adults but free for children under sixteen and recognized groups of students) has been made. The revenue is devoted exclusively to the improvement of the collections, and it is interesting to note that the decrease in attendances is not nearly so great as was expected.

Student Exchange

DURING the summer vacation of 1959 the number of students sent and received under the programme of the International Association for the Exchange of Students for Technical Experience of Great Britain increased to 854 students received, and 837 students sent; the corresponding figures for 1958 were 829 and 774, respectively. Some 366 British companies took part in the scheme. In April 1959 a general meeting of representatives of affiliated universities, colleges and companies was convened to consider the future organization of the Association, in Great Britain. It was decided to establish an independent council to control the Association, and the legal formalities are now proceeding. It is anticipated that the new Council of the Association will operate from September 1960. Greece has been accepted as a full member of the Association, and Poland and Tunisia have been admitted as associate member countries for one year. Further information about the Association can be obtained from J. Newby, superintendent of vacation studies, Imperial College of Science and Technology, London, S.W.7.

Scottish Field Studies Association

THE Scottish Field Studies Association has announced its programme for the forthcoming season April–September. The courses will be based on the Garth Field Centre and the Isle of Ramsey, and accommodation fees will be up to 4½ guineas a week. Members of local scientific societies qualify for bursaries of £3 (for a course lasting a week) from a fund made available by the Carnegie United Kingdom Trust. Further information can be obtained from the Scottish Field Studies Association, c/o Department of Botany, The University, Glasgow, W.2.

Symposium on Herbicides and the Soil

The British Weed Control Council has arranged a symposium on Herbicides and the Soil, which will be held in the Clarendon Laboratory, Parks Road, Oxford, on April 7. Four papers will be presented. The first will be by Prof. L. J. Audus (Bedford College, London) on "Microbiological Breakdown of Herbicides in Soils". Prof. W. Fletcher (West of Scotland Agricultural College, Glasgow) will speak on "The Effects of Herbicides on Soil Micro-Organisms", and Dr. G. S. Hartley (Chesterford Park Research Station) on "Physico-chemical Aspects of the Availability of Herbicides in Soils". The symposium will be concluded by Dr. Ir. W. van der Zweep (Wageningen), who will speak on "Persistence in the Soil of Some Important Herbicides". Further information can be obtained from G. R. Sagar, Unit of Experimental Agronomy, Department of Agriculture, University of Oxford.

Announcements

Dr. D. A. Senior, whose appointment to the newly created post of scientific attaché to the British Embassy in Moscow was announced in *Nature* of April 11, 1959, p. 1018, left London to take up his post on January 31. Dr. Senior has no specific technical assignment in Moscow, but will cover the broad field of science and technology. His aim is to promote good relations and understanding between the two countries in this field and to facilitate exchanges of information and people.

Dr. A. D. Macdonald, Leech professor of pharmacology in the University of Manchester, has been appointed Officier de l'Ordre de la Santé Publique by the French Minister of Health. Prof. Macdonald, one of the members of the Pharmaceutical Society's Council nominated by the Privy Council, has been for two years president of the British section of the Franco-British Pharmaceutical Commission, a body set up as a result of a suggestion made by Sir Winston Churchill that members of the same professions on each side of the Channel should get to know one another better.

Dr. A. W. Meschkat, of Hamburg, has been appointed as Food and Agriculture Organization regional fisheries officer for Africa. He will assist governments to develop fish production of the seas off East and West Africa and of the lakes and rivers of Central Africa.

Mr. A. L. Jewell, assistant curator of Haslemere Museum, has been appointed to a newly created post of exhibitions officer at the Royal Botanic Gardens at Kew. Mr. Jewell will be joining the staff of the Keeper of Museums at Kew and his special concern will be to re-display existing exhibits.

Dr. R. H. Hedley, a senior scientific officer in the Department of Zoology, British Museum (Natural History), has been awarded the 1960 New Zealand National Research Fellowship and will work on some aspects of the biology and systematics of marine allogromoid Foraminifera (Protozoa) living in New Zealand coastal waters.

The Corday-Morgan Award, consisting of a silver medal and a monetary prize of 200 guineas, is made annually to a chemist of British nationality who, in the judgment of the Council of the Chemical Society, has published during the year in question the most meritorious contribution to experimental chemistry, and who has not, at the date of publication, attained the age of thirty-six years. Copies of the rules governing the Award may be obtained from the General Secretary of the Society. Applications or recommendations in respect of the Award for the year 1959 must be received not later than December 31, 1960, and applications for the Award for 1960 are due before the end of 1961.

The sixty-fifth annual congress of the South-Eastern Union of Scientific Societies will be held at Ipswich during April 22–25. Further information can be obtained from Mr. Frank Edwards, 53 The Drive, Shoreham-by-Sea, Sussex.

The annual spring conference of the Institute of Metal Finishing will be held in the Grand Hotel, Scarborough, during April 26–30. Further information can be obtained from the Honorary Secretary, Institute of Metal Finishing, 32 Great Ormond Street, London, W.C.1.

The spring conference of the X-Ray Analysis Group of the Institute of Physics will be held in the main Chemistry Lecture Theatre, University of Reading, during April 8–9. The subject will be "The Borders of X-ray Analysis". Further information can be obtained from Dr. P. T. Davies, "Shell" Research, Ltd., Thornton Research Centre, P.O. Box 1, Chester.

A symposium, sponsored by the Office of Ordnance Research U.S. Army, will be held in the Inorganic Chemistry Laboratory, Oxford, during April 5–6, on Plastic Crystals and Rotation in the Solid State. Further details can be obtained from L. A. K. Staveley, Inorganic Chemistry Laboratory, South Parks Road, Oxford.

The Ergonomics Research Society is holding its annual conference at the University of Cambridge during March 28–31. The programme will include two sessions on "Ergonomics in the Armed Forces", a session on "Ergonomics in the Netherlands", and a symposium on "Factors in Prolonged Work, especially Inspection". Further information can be obtained from the conference secretary, Dr. S. Griew, University of Bristol, Department of Psychology, 22 Berkeley Square, Bristol 8.

The Turkish Bibliography of Articles appearing in Turkish Periodicals for January–March 1959 is provided with a foreword in French as well as Turkish, and the classification, too, is now given in French as well as in Turkish. Titles of the periodicals covered are listed in French and Turkish, and each entry is provided with a French translation of the title; titles are arranged according to the Dewey Decimal Classification up to the first two or three figures only.

A research scholarship in the use of light alloys in structural engineering is being offered by the Institution of Structural Engineers in collaboration with the Aluminium Development Association. The duration of the scholarship will be for two years and the value £600 per annum. The award is made every three years as from October 1. Further information can be obtained from the Secretary of the Institution of Structural Engineers. Completed application forms should be sent to reach the Secretary by March 31.

INDUSTRIAL ARCHÆOLOGY

THE conference held at the London School of Hygiene and Tropical Medicine on December 12 was the first event organized by the recently formed Research Committee on Industrial Archæology of the Council for British Archæology. The large attendance of some 180 people was very encouraging, and confirms the Council in its belief that considerable interest exists as well as concern about the fate of industrial monuments.

Dr. J. N. L. Myres, president of the Council, took the chair, and the conference opened with the reading of a message from the Minister of Works. The first paper was by Mr. M. M. Rix, staff tutor in architectural history in the University of Birmingham, on "Industrial Archæology as illustrated in the West Midlands". This area is a particularly rich field, and Mr. Rix described many fine examples such as Ironbridge and Coalbrookdale, Telford's canal aqueducts, and the earliest existing iron-framed building, a former flax-spinning mill at Shrewsbury.

The second paper, by Mr. J. M. Palmer, was on "The Stamford Canal: a Seventeenth Century Navigation". His chief purpose was to show how the history of a canal, the very site of which can only with difficulty be identified, may be reconstructed by a thorough search of national and local records. The paper was introduced by Mr. Maurice Berrill, honorary secretary of the Railway and Canal Historical Society.

The afternoon session began with a paper by Prof. A. W. Skempton, of the Imperial College of Science and Technology, London, on "Structural Development of the First Iron-framed Textile Mills". He showed how iron-framing was originally developed because of the danger of fire in early factory buildings. The development was one of very great importance as it culminated in the steel-frame buildings of the first examples of modern architecture designed by Louis H. Sullivan in Chicago towards the end of last century. Prof. Skempton showed how skilfully he had combined study of actual buildings and documentary records to establish the sequence of mills in Derbyshire and at Shrewsbury and Salford.

The remainder of the afternoon session was devoted to three short papers. The first was a brief note by Mr. C. W. Phillips, read in his absence owing to illness, on the Ordnance Survey in relation to the recording of industrial archæology. Mr. Phillips, who is archæology officer to the Ordnance Survey, pointed out that surveying and recording are being extended to include early industrial remains. He also made it clear that the records compiled by the Ordnance Survey on such sites will be available to research workers. Dr. P. M. G. Eden, of the Royal Commission on Ancient Monuments, gave a most practical short address on the technique of recording industrial monuments. He encouraged amateur field groups by emphasizing that preliminary work in recording often serves as a basis for specialist studies. Mr. J. M. Richards, editor of the *Architectural Review*, read the final paper on "Visual Aspects of the Subject and the Æsthetic and Landscape Value of Early Industrial Monuments", in which he distinguished between the architectural quality of industrial buildings and their part in the landscape in so far as it was a creation of man. Mr. Richards's thesis that the best of our early industrial buildings mark the beginning of the functional tradition in architecture is already well known.

In the discussions which were held after the papers during both morning and afternoon sessions a keen concern could be observed with how the recording of industrial remains might be carried out and appropriate examples preserved. The need for the co-ordination of the activities of the different societies working in the field of industrial archæology was emphasized, as was the necessity for an informed public opinion which could bring pressure to bear on the appropriate authorities. It was even suggested that the Royal Commission on Historical Monuments should appoint additional staff to deal with the survey of industrial remains. Hopeful developments were referred to such as the action of Allied Ironfounders in clearing the site of the old Coalbrookdale ironworks, the first scientific excavation of an industrial site by the British Museum at the Longton Hall porcelain factory, and the appointment of an archæological officer in the Staffordshire County Planning Department.

The conference closed with a summary by Mr. Maurice Barley, secretary of the Council for British Archæology, at the conclusion of which he read a draft resolution. A discussion followed in which the chief points made were the necessity to interest industry in the work of record and preservation and to emphasize the educational importance of industrial archæology when so much was being heard of the need for increased technical and scientific training.

The resolution as finally passed declared that the conference was deeply impressed by the need for formulating a policy for recording and, where necessary, preserving early industrial monuments. The Research Committee on Industrial Archæology was further instructed by the resolution to find opportunities to discuss with central and local authorities, as well as with industry and unofficial bodies, the question of record and preservation.

The Research Committee proposed as a first step to prepare a handbook of industrial archæology which would serve as a guide to societies and individual research workers anxious to carry out surveys of industrial remains. Plans are now being made to initiate a pilot survey either of a region or of a particular industry. It is also hoped to hold regional conferences, and as soon as possible to organize courses at which some training in recording and interpreting industrial sites can be given.

The immediate task of the Committee is to establish closer contact between the individual research workers and societies which have been working in different parts of the field covered by industrial archæology and to attempt to direct their efforts towards the creation of a single discipline. The work of the Committee, if successful, will go a long way towards establishing the study of the history of technology on a more respectable footing in Britain as well as supplementing the work of economic and social historians. Much depends on the degree of interest which can be aroused among scientists and technologists, without whose assistance it will be virtually impossible to go on to specialized surveys of particular industries. The Committee already includes archæologists, historians, architects, geologists and technologists, but would warmly welcome the co-operation of more people with specialized knowledge of mining, quarrying, textiles, metallurgy, chemicals, civil and mechanical engineering or any of the other innumerable subjects in this vast field of industrial archæology. E. R. R. GREEN

NINTH CANADIAN HIGH POLYMER FORUM

THE ninth Canadian High Polymer Forum, held at the Guild Inn, Toronto, during October 26–28, was attended by 142 chemists from Great Britain, the United States and Canada. The chairman was M. H. Jones (Ontario Research Foundation) and the session chairmen were S. Bywater (National Research Council), H. H. G. Jellinek (Essex College), M. Rinfret (University of Montreal) and G. Olah (Dow of Canada).

At the business meeting on October 26 the officers for the tenth Forum were elected: *chairman*, L. A. McLeod, Polymer Corporation; *programme chairman*, K. E. Russell, Queen's University, Kingston, Ontario; *secretary-treasurer*, D. A. I. Goring, Pulp and Paper Research Institute.

At the banquet on October 27, the guest speaker, C. H. Bamford, of Courtaulds, Maidenhead, spoke on "Patterns in Reactions and Polymers". He said that detailed information is now available concerning transfer reactions of polymer radicals with a variety of substrates. For a hydrocarbon substrate such as ethylbenzene, the rate constants for the hydrogen abstraction process involving a series of polymer radicals are fairly accurately proportional to the rate constants for the corresponding reactions with toluene. In these reactions with hydrocarbon substrates, polar factors are very small. With ferric chloride, butyl mercaptan or carbon tetrabromide as substrates, a logarithmic plot of rate constants for the transfer reaction against rate constants for the corresponding reaction with toluene gives a number of scattered points. The pattern of points is, however, very much the same in all three cases. With triethylamine as substrate an 'inverse' pattern is obtained. Patterns of the first type are obtained in addition reactions involving the same polymer radicals and a number of vinyl monomers.

The observed patterns can be interpreted in terms of polar effects, the rate constant depending considerably on the extent to which the substituent in the radical is electron-withdrawing or electron-releasing. From a quantitative treatment, Dr. Bamford concluded that it is possible to express the rate constant for the transfer reaction of a radical with a given substrate in terms of the rate constant for transfer with toluene and the Hammett σ constant for the radical. Predictions based on this quantitative theory are in excellent agreement with experiment.

The main sessions began with a paper by J. K. N. Jones (Queen's University) on "Some Problems in Polysaccharide Chemistry". In pointing out some of the difficulties involved in complete structural determinations of polysaccharides, he said that it is not always possible to decide whether traces of sugars occurring with the main hydrolysis products of polysaccharides were part of the original macromolecule. Degrees of branching can be readily obtained using the Haworth methylation technique, but frequently it is almost impossible to achieve 100 per cent methylation of a polysaccharide. The major problem in this field is to imitate the action of enzymes on sugars and sugar derivatives to produce polymers similar to those found in plants and animals.

B. L. Funt and F. D. Williams (University of Manitoba) in their paper on "Retardation and Inhibition of Methyl Methacrylate Polymerization" described investigations of the effect of benzoquinone on methyl methacrylate polymerization using quinone and initiator labelled with carbon-14. They observed a transition from retardation to inhibition at a critical concentration of benzoquinone. The Monday morning session closed with a short colour film on polymer interactions made available by W. F. Busse, Du Pont Co., Wilmington.

The first in a series of papers on polymer degradation was given by H. A. Kraessig and J. Neal (Industrial Cellulose Research), who discussed "The Degradation of Cellulose by Megavolt Electrons". They showed that at low dose-rates the number of chemical bonds broken is a linear function of the dose, and the sensitive volume corresponding to cleavage of a single bond is close to the volume of a monomer unit. Experiments on wet cellulose indicate that water has a considerable protective action. H. H. G. Jellinek (Essex College) and W. A. Schlueter described work performed at the University of Cincinatti on "The Photodegradation of Polyacrylonitrile in Solution", using light of wave-length 2537 Å. The rate of degradation *in vacuo* is proportional to the light intensity and the number of broken bonds is less than 10^{-3} per quantum absorbed. W. C. Schneider (American Cyanamid) spoke on "The Thermal Stability of Polyacrylonitrile". At 240° in the absence of oxygen he observed that the polymer breaks down very rapidly giving a complex mixture of products, but in the presence of oxygen a more controlled reaction gives water, ammonia and hydrogen cyanide as the only volatile products. J. R. Schaefgen (Du Pont) presented a paper on "The Thermal Degradation of Poly-*p*-xylylene". The rate of degradation was measured in a chlorinated aromatic solvent in the range 285–321°. Degradation is random, and the activation energy is 58 kcal./mole. Anthracene decreased the rate of degradation, but common transfer agents are inactive.

R. J. Orr (Polymer Corporation) presented a paper on "Thermochemical Aspects of Free Radical Butadiene-Styrene Copolymerization". A treatment of the thermodynamics of copolymerization has been devised which can be applied to high-conversion material. The sum of the entropy changes for the two heteropolymerization steps was found to be about 50 entropy units/mole assuming that the residual entropy contributed by the glassy state is zero.

C. Booth and L. R. Beason (Shell Chemical) gave a paper on "Statistical Treatment of Polymer Fractionation Data". A styrene-butadiene copolymer was fractionated and the fractionation data subjected to a simple binomial analysis. The resulting distribution of molecular weight was in good agreement with that calculated from the kinetics of the emulsion system. J. A. Manson, W. W. Graessley and L. M. Hobbs (Air Reduction Co.) described "The Determination of the Breadth of Molecular Weight Distribution in Polyethylene by an Irradiation Technique". Samples of high-pressure and low-pressure polyethylene were irradiated using a cobalt-60 source and were analysed for soluble and gel fractions. From the results it is possible to calculate weight and number average molecular weights of the original polyethylene samples.

A. Rezanowich and D. A. I. Goring (Pulp and Paper Research Institute) have investigated "The Polyelectrolyte Properties of a Lignin Sulphonate Microgel". Their measurements of the polyelectrolyte expansion of fractions of sodium lignin sulphonate indicate a microgel structure for the macromolecule. They developed a theory assuming that the microgel structure has free charges only on the surface and showed that it agreed fairly well with experiment.

D. J. Worsfold and S. Bywater (National Research Council) spoke on "Some Properties of Poly-α-methylstyrene produced by Anionic Polymerization". They have made a thorough molecular weight analysis of poly-α-methylstyrene samples produced using sodium naphthenide as catalyst. One important result is the intrinsic viscosity–molecular weight relationship for polymer samples of very sharp distribution.

M. Senez and H. Daoust (University of Montreal), in their paper on "Heat Parameters for Poly*iso*butylene Solutions", compared heat parameters determined for the poly*iso*butylene–chlorobenzene system by calorimetry and by the viscosity method of Fox and Flory. The results fit the Fox and Flory treatment of viscosity data.

W. Heller and M. Nakagaki (Wayne State University), in "The Exact Theory of the Scanning Method for determining Particle Sizes from Light Scattering", gave accurate calculations of the angular positions of maxima and minima for non-absorbing spheres for the large relative refractive index of 1·20. The results for other relative refractive indexes can now be calculated fairly readily.

T. Gillespie (Dow Chemical) presented papers on "The Limited Flocculation of a Colloidal System by a Water Soluble Polymer" and "The Rheology of a Polystyrene Latex thickened with Methylcellulose". His results on the flocculation of styrene–butadiene latex by methylcellulose indicate that the stabilization of a hydrophobic colloid by a hydrophilic colloid is due to changes in the balance of the flocculation and deflocculation processes. Methylcellulose thickens a polystyrene latex by causing a reversible partial flocculation.

A. Novak and E. Whalley (National Research Council) presented data on "The Infra-red Spectrum of Polyformaldehyde" and showed that these data could be interpreted on the assumption of a helical model for the polymer.

E. H. Immergut, G. Kollmann and A. Malatesta (Dunlop Research Centre) reported results on "The Cationic Copolymerization of Propylene and Isoprene". They prepared soluble copolymers under carefully controlled conditions using aluminium chloride as catalyst at −78° (molecular weight range 4,000–10,000). Reactivity ratios for propylene and isoprene are approximately 0·23 and 0·5. M. H. Jones, U. Martius and M. P. Thorne (Ontario Research Foundation) discussed "The Polymerization of 1-Butene by Metal Alkyl–Titanium Halide Catalysts". They reported the results of chemical and X-ray analyses of the complex catalysts produced by the interaction of aluminium triisobutyl or lithium *n*-butyl with titanium trichloride or tetrachloride. Kinetic results for the polymerization of butene-1 using aluminium triisobutyl–titanium trichloride were given ; the products were of very high molecular weight (intrinsic viscosity between 5 and 6).

C. H. Bamford, in a paper on "Termination by Primary Radicals in Vinyl Polymerization", said that when the initiator concentration is high, a plot of rate of polymerization of styrene versus monomer concentration is curved. This can be quantitatively accounted for by assuming termination of some growing polymer radicals by primary radicals from the initiator. The velocity constant for primary radical termination is about sixty times that for mutual termination. The interaction of unlike radicals was also discussed by C. Sivertz and Y. Ebisuzaki (University of Western Ontario) in a paper on "The Measurement of the Cross-Termination Velocity Constants for Picrylhydrazyl and Alkyl Radicals". They studied the thermal decomposition of azobisisobutyronitrile at such low concentrations that the combination of free cyano-alkyl radicals competed with the reaction with diphenylpicrylhydrazyl. The relationship between the two velocity constants was derived.

L. E. Coleman and J. F. Bork (The Lubrizol Corporation) spoke on "The Reactivity Ratios of N-Vinyl Oxazolidone and N-Vinyl Pyrrolidone with Vinyl Monomers". N-Vinyl oxazolidone copolymerizes well with vinyl chloride and vinyl acetate but not with styrene and methyl methacrylate ; N-vinyl pyrrolidone is more reactive than N-vinyl oxazolidone. W. E. Walles, W. F. Tousignant and T. Houtman (Dow Chemical) have studied "Poly-N-vinyl, 5-Methyl 2-Oxazolidone (PVOM) a New Complexing Polymer". PVOM of molecular weight 150,000 is soluble in water below 40° and insoluble at higher temperatures. This behaviour is explained in terms of a change from a structure which presents largely hydrophilic groups to the solvent to one which is almost entirely hydrophobic.

R. J. Ceresa and F. H. Cotton (National College of Rubber Technology, London), in presenting a paper on "The Mechanico-Chemical Modification of High Polymers", said that cold mastication of elastomers in the presence of 0·1 per cent aluminium isopropoxide eventually leads to gels ; under similar conditions a mixture of polyvinyl acetate and polyethylene may give a fair yield of block copolymer.

R. J. Richardson (Atomic Energy of Canada) spoke on "Radiation Grafting of High Polymers". Nylon tenting fabric was irradiated with gamma-rays in the presence of styrene to give polystyrene grafts largely on the surface of the nylon, with a resultant improvement in its weathering properties. Irradiation of nylon and terylene in the presence of acrylonitrile and vinyl pyrrolidone gave a slight improvement in dyeing response.

J. R. Tichy (Maine Medical Center), in his paper on "The Polymerization of Phosphorus Pentachloride and Urea", presented analytical data on the products of this complex polymerization. In the last paper presented, R. W. Lenz and W. K. Carrington (Dow Chemical) discussed "The Preparation of Phenylene Sulphide Polymers by the Macallum Polymerization". The reaction of *p*-dichlorbenzene with sulphur and sodium carbonate at 300–350° to give a high molecular weight phenylene sulphide polymer probably proceeds partly by a direct attack of sulphur diradicals on the dihalide and partly by attack of sodium sulphide formed by reaction of sulphur with sodium carbonate.

K. E. RUSSELL

DIELECTRIC DEVICES

AN informal residential conference on dielectric devices was held in the Electrical Engineering Department of the University of Birmingham during September 14–17, 1959, inclusive, and was attended by representatives from universities, Government establishments and industry. The aims of the conference were to give those participating a broad overall picture of this sector of solid-state physical electronics, to discuss present trends and new ideas connected with the investigation and exploitation of dielectrics, and to stimulate research on dielectric materials and devices. In an attempt to achieve these aims each session was opened with an invited general paper which reviewed physical principles and assessed practical progress in exploitation; each session then continued with shorter papers describing current research on the properties of materials and the mechanisms of devices.

The first paper of the conference opened the session on masers and parametric amplifiers. This was given by I. M. Ross (Services Electronics Research Laboratories, Harlow), who reviewed the mechanisms of these devices and compared their more important characteristics such as gain bandwidth products and noise figures. J. C. Walling (Mullard Research Laboratories, Salfords) then described the paramagnetic resonance characteristics of chromium-doped potassium cobalticyanide and the advantages of maser operation using 'push–pull' and 'push–push' pumping. Experimental realization of both types of double pumping had been obtained in a cavity maser at a signal frequency of 2,900 Mc./s. with respective root-gain bandwidth products of 12 and 19 Mc./s. in the two cases.

In the following paper, by B. Bölger, N. J. Robinson and J. Ubbink (Philips, Eindhoven), read by J. Ubbink, the characteristics of a 1,420 Mc./s. maser were described. A three-level maser using potassium cobalticyanide at 1·4° K. with a pump frequency of 3,850 Mc./s. and a signal frequency of 1,420 Mc./s. had been constructed. A root-gain bandwidth product of 2·7 Mc./s. with a limiting power of 2×10^{-7} W. had been obtained. The final paper of this session dealt with parametric amplification and was given by L. E. Cross (Electrical Research Association, Leatherhead), who considered the use of a ferroelectric material above its Curie temperature as a possible variable reactance for this purpose. The electro-mechanical effects in ferro-electrics were briefly discussed and saturation functions derived for barium titanate and glycine sulphate. Measurements showed that glycine sulphate could not be used at 500 Mc./s. due to enhanced dielectric losses near the Curie temperature.

The second session was opened by G. F. J. Garlick (University of Hull), who reviewed the physical mechanisms of photoconductivity and luminescence. H. G. Lubszynski (E.M.I., Hayes) then explained how the use of an electron beam for making contact to a semi-conductor offers advantages in the case of near insulators because it allows thin films of large cross-sectional area to be used with less danger of shorting. Organic luminescence and the scintillation counter formed the subjects of the next two papers. In the first of these, J. B. Birks (University of Manchester) discussed the fast and slow components of scintillations in organic materials. The former was attributed to direct singlet-state excitation, was subject to primary quenching, and hence depended on the nature of the particle. The latter was attributed to ion recombination leading to excitation of metastable triplet states, was less subject to primary quenching, and was largely independent of the nature of the particle. P. E. Gibbons and D. C. Northrop (Services Electronics Research Laboratories, Baldock) then described experiments on the long-lived decay components of anthracene scintillations showing that the characteristic times are independent of exciting particles and temperature. These and other experiments on impure anthracene show that these components probably derive from some co-operative lattice property and not a molecular one.

The opening paper of the third session was given by G. Diemer (Philips, Eindhoven), who reviewed present and potential applications of luminescence and photoconductivity in power amplification. The first research paper of the session was read by P. K. Weimer for E. E. Loebner (R.C.A., Princeton) and explained how it should be possible to escape the gain-bandwidth limitations of currently available luminescence amplifiers by using luminor elements themselves capable of modulation and amplification. The second research paper was given by J. Woods (G.E.C., Wembley), who described experiments showing that cadmium sulphide crystals doped with 1–2 per cent copper are *p*-type. Measurements of electrical conductivity, σ, Hall coefficient, R, and thermoelectric power, α, had been made from 95° K. to 380° K., and suggested transport via impurity-levels. At 300° K. it was found for $\sigma = 0 \cdot 18$ ohm^{-1} cm.$^{-1}$ that $p = 1/Re = 5 \cdot 6 \times 10^{14}$ cm.$^{-3}$, $\mu = R\sigma = 20$ cm.^{2} volt^{-1} sec.$^{-1}$, and $\alpha = 22$ μV./°C.

Space-charge-limited current in dielectric crystals formed the topic for the fourth session. The opening paper of this session was given by G. T. Wright (University of Birmingham) and reviewed the mechanisms of space-charge-limited current in dielectrics and, on the basis of a simplified theory and available experimental data, assessed tentatively potential fields of application of space-charge-limited dielectric devices. In a short following paper, A. A. Kayali (University of Birmingham) described measurements of the temperature dependence of forward current of a number of space-charge-limited cadmium sulphide dielectric diodes. In diodes with a small trap density the current increased slowly as the temperature was lowered from 400° K. to 90° K. due to the increase of electron mobility at the lower temperatures; above room temperature there was little variation of characteristics. In most cases the square-law dependence of current upon voltage was obeyed over this whole temperature-range. High-speed switching characteristics of the diodes were described in a paper by A. M. Conning (University of Birmingham). For both 'switch-on' and 'switch-off' operation steady-state conditions were reached in a time less than 3 mμsec., the response time of the measuring equipment; charge storage effects in the diodes were undetectable. The final paper of this session was given by G. T. Wright and discussed the design of a proposed amplifying dielectric triode, which should possess a high input resistance, a large gain-bandwidth product, and be relatively insensitive to temperature changes. Calculations showed that the presence of shallow trapping levels ($< 0 \cdot 30$ eV.) should result in the mutual conductance at high frequencies (> 10 Mc./s.) being many times greater than at audio frequencies.

The opening paper of the fifth session was given by W. J. Merz (R.C.A., Zurich) on the subject of ferro-electricity. Present ideas of basic mechanisms in 'soft' and 'hard' ferro-electrics were reviewed and outstanding problems such as nucleation and losses above the Curie point considered. In the following paper, by K. W. Plessner (British Dielectric Research, London) and R. West (United Insulator Division, T.C.C., Chessington), the influence of the chemical composition of high permittivity ceramics upon their electrical properties was discussed. The application of chemical processes on an industrial scale was then considered. J. H. Bruce and J. R. Balmer (Radio Research Establishment, Malvern) then discussed the need for thin-film capacitors and the suitability of an evaporation method for producing these. Experimental techniques and results for silicon monoxide capacitors were described. The last paper of the session was given by R. C. Kell (G.E.C., Wembley), who discussed piezoelectric ceramics. It had been found that niobate ceramics retained their piezoelectric properties at temperatures considerably higher than ceramics based on barium titanate and that their properties showed less variation with temperature. In particular, sodium–cadmium and lead–barium niobates were more suitable than barium titanate ceramics for use in vibration detectors, ultrasonic generators, and resonators for filter networks.

The final session of the conference included contributions from S. Duinker (Philips, Eindhoven) on a square-loop ferrite device for the fast scanning of electroluminescent cross-bar systems; from D. W. G. Ballentyne (Siemens Ediswan, Harlow) on the possible explanation of electroluminescence as a disorder phenomenon; from R. M. Glaister (G. V. Planar, Ltd., Sunbury) on relaxation polarization dielectrics; from E. A. D. White (G.E.C., Wembley) on the effects of additives on the properties of barium titanate ceramics; from J. C. Burfoot (Queen Mary College, London), who discussed switching in ferro-electrics; from Mr. F. H. Stieltjes (Philips, Eindhoven), who discussed losses in ferro-electrics with particular reference to their use in parametric amplifiers; and G. T. Wright on the trap content of dielectrics with particular reference to the characteristics of dielectric diodes.

The conference emphasized that very great potentialities exist for the exploitation of dielectrics in devices although only limited practical progress has yet been made. There is no doubt, however, that the number and diversity of outstanding problems make this a most attractive field for both fundamental and applied research.

G. T. WRIGHT

THE NATIONAL RESEARCH DEVELOPMENT CORPORATION OF GREAT BRITAIN

IN view of the stress laid on the work of the National Research Development Corporation by Prof. C. F. Carter and Prof. B. R. Williams in "Science in Industry" and of the interest in the Corporation which Lord Hailsham has already shown, the Corporation's annual report for the year July 1, 1958–June 30, 1959, will doubtless be closely examined by scientists and technologists as well as industrialists (National Research Development Corporation. Report and Statement of Accounts for the year 1st July, 1958, to 30th June, 1959. Pp. ii+22. London: H.M. Stationery Office, 1959. 1*s*. 3*d*. net). This year's report is limited to a factual account of the year's work, but the report comments on the greater attention now paid to the Corporation's work by the scientist and industry as well as by the general public, and confidence is expressed that the Corporation's unique experience will enable it to play an ever increasing part in the application of scientific ideas to industry. Revenue from inventions rose to £189,761, and there was also a non-recurring item of £92,978 from sale of patent rights. Government departments and research councils assigned patent rights in 119 cases, compared with 86 in 1958–59, 59 of the total of 185 coming from universities and 5 from industrial research associations, compared with 49 and 1, respectively, out of 147 in 1957–58. Of 681 inventions communicated to the Corporation during the year, compared with 612 the previous year, 287 were from Government departments and research councils, 27 from Commonwealth official organizations, 60 from universities, 8 from industrial research associations and 296 from private firms and individuals, 263 in the United Kingdom. Holdings of British and foreign patent applications totalled 2,794, including 419 United Kingdom patent applications and 580 granted patents, 820 overseas applications and 975 granted patents.

Among new projects initiated during the year or reaching a stage suitable for report are Dr. I. E. Bush's automatic apparatus for chemical treatment and scanning of chromatograms, which has speeded up procedure considerably; the development of the new antibiotics called the cephalosporins, particularly cephalosporin *C*, which is resistant to destruction by penicillinase; Prof. E. C. Cherry's television compression system using a variable scanning velocity so adjusted as to keep the transmitted frequencies within a desired bandwidth. An experimental system based on a 30-line picture has been constructed, and a further experimental system operating on 405 lines is being developed. A contribution has been made towards the cost of equipment to assess a proposal for an improved rolling mill, using rolls supported in hydrostatic bearings, and the Council decided in September 1958 to sponsor the development of Mr. C. S. Cockerell's inventions relating to "Hovercraft", and has formed a subsidiary company, Hovercraft Development, Ltd., to be responsible for its interest in this project. Financial assistance is being provided to complete the development of equipment capable of continuously processing hides and so giving increased capacity allied to smooth-running production and control. As a result of arrangements made by the Corporation to develop and exploit a new type of ditch cleaning media, a British manufacturer is building five prototypes, and the test results of the National Physical Laboratory on the robust and reasonably effective stabilizer designed in 1956 have now been checked on a full-scale ship.

Reference is also made to further developments in a process for producing acetylene by partial combustion of methane, to satisfactory negotiations for financial support of the computer-controlled machine tool project to be taken over by more appropriate organizations ; the completion of a further design study permitting detailed assessment of the economic advantage of Fanshawe's oil-well drilling rig, and of the initial three-year programme of work on the ion-exchange membrane project, under which a process has been developed for continuous electro-chromatography. Considerable further development will be required before the hydrogen–oxygen fuel cell can be launched on a commercial basis. New licensing arrangements were set up with a leading ice-cream manufacturer, who is now in production for the project for a freezing mill after treatment with ultra-sonic waves and pouring into waxed paper containers, and the process appears to offer prospects in the Middle East. Following successful testing and demonstration of the prototype flexible container for transporting oil, seven others have been ordered for use in different parts of the world.

SOLAR STILLS IN IRAQ

By Dr. A. V. BRANCKER
College of Science, University of Baghdad

EXPERIMENTS with solar stills and related units have been in progress at the College of Science, Baghdad, to provide fresh water for Bedouin communities, and to investigate the concentration of natural to heavy water.

Several designs of solar still were tested. Fig. 1 shows a still with a hemispherical 'Perspex' canopy. The base flange was held by screw clips on a gasket in a circular water channel. The complete unit included a flat-plate collector used as a preheater to increase the output of distilled water. The hemispherical still and a prismatic type with a glass canopy have been in continuous operation without maintenance since 1956. Only recently have fine superficial cracks appeared in the 'Perspex'. In other respects these stills, of essentially simple design, have been satisfactory. Curves of water yield versus time and temperature versus time curves for the hemispherical 'Perspex' and prismatic glass stills, with no preheating, are plotted in Fig. 2. The effect of dropwise condensation on the 'Perspex' unit and back reflexion is shown by the relative positions of the curves. The total water output and the dimensions of the stills are given in Table 1.

Table 1

Solar still	Depth of water	Yield of water (litres/sq. m./day)
Hemispherical canopy, radius 1·5 ft.	¾ in.	2·5
Prismatic canopy, 6·0 ft. × 2·2 ft.	¾ in.	3·6

On the basis of 3·60 litres or 0·79 gal. per square metre per day, the output, for a coverage of 1 acre, would be some 3,200 U.K. gal./day. Similar results were obtained by Lof[1] at 0·69–1·07 gal./sq. metre/day. In alternative units, the amount of water from a solar still is approximately 1 lb./sq. ft./day.

In addition to providing fresh-water for small communities, in remote areas, another application is being considered. Thus, natural water contains 1 part of heavy water in 6–7,000 parts ; therefore, very large quantities of water have to be vaporized or processed at heavy fuel costs. The relative volatility of heavy and ordinary water increases with decreasing temperature ; this suggests the possibility of using solar evaporation and fractionation, which can proceed at relatively low temperatures and no fuel costs. One method of investigation is based on the flat-plate solar heater shown in Fig. 1, from

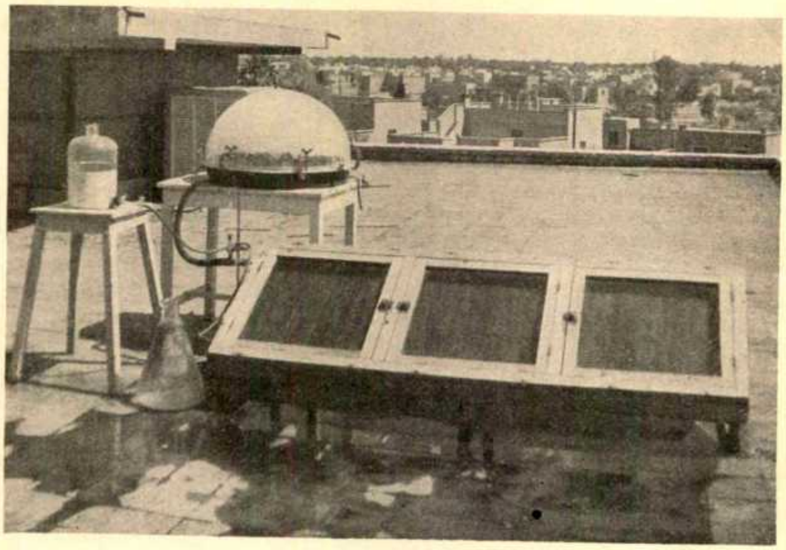

Fig. 1

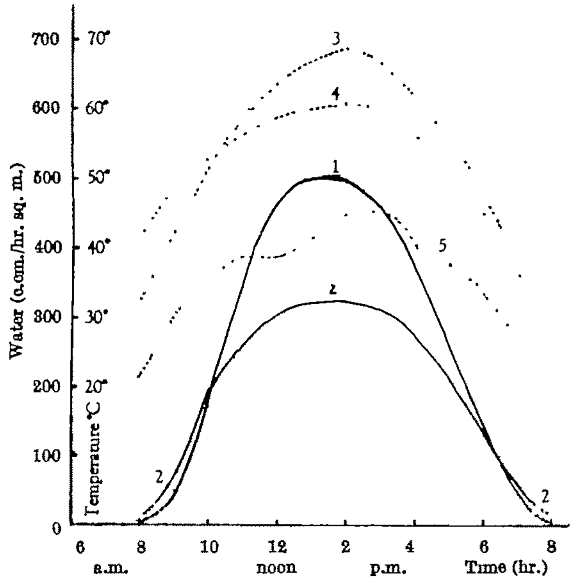

1, 2, Water yields. 3, 4, 5, Temperatures
1, 3, Glass 2, 4, 'Perspex' 5, Air temp.

Fig. 2

which steam can be obtained. An alternative method is a solar-heated counter-current air–water stripping system. Using a packed tower, water is condensed from hot exit air at saturation humidity. It is not suggested that by solar evaporation methods a full recovery of heavy water is possible, but some preliminary concentration may be obtained for more conventional processing. Again, very large quantities of water would have to be evaporated, but it is precisely this condition which would be necessary in large-scale solar demineralization of brackish water. The objective, therefore, if possible, is to combine two needs.

The physics of evaporation in solar stills is related to the more complex problem encountered in studies of atmospheric evaporation, for which many equations have been derived. It is only possible to outline some methods which can be used. In Table 2, for example, is given a known comparison of heat and mass transfer equations using dimensionless groups.

Table 2

Heat transfer	Mass transfer
(1) Surface conditions	(1) Equimolecular counter-diffusion
$q = h\Delta T$	$N = k_D\Delta P/RT$
$q = -k\,\delta T/\delta x$	$N = -(D_a/RT)\,\delta P/\delta x$
$\theta = T/\Delta T$	$B = P/\Delta P$
$x^1 = x/L$	$x^1 = x/L$
$hL/k = \delta\theta/\delta x^1$	$h_D L/D_a = \delta\beta/\delta x^1$
$\theta = f(x^1, Re, Pr)$	$\beta = f(x^1, Re, Sc)$
$hL/k = f(Re, \nu/\alpha)$	$h_D L/D_a = f(Re, \nu/D_a)$
(2) Energy equation	(2) Continuity equation
$\rho\, DH/Dt - DP/Dt = Jk\nabla^2 T$	$DC/Dt = \mathbf{u}\nabla C + \delta C/\delta t = D_a\nabla^2 C$
$t^1 = vt/L$	$t^1 = vt/L$
$P^1 = P/\rho v^2$	$C^1 = C/\rho$
$H^1 = H/JC_p\Delta T$	$\mathbf{u}^1 = \mathbf{u}/v\ldots.$
$DH^1/Dt^1 - \dfrac{v^2}{JC_p\Delta T}DP^1/Dt^1 = \dfrac{\alpha}{vL}\nabla^2\theta^1$	$\delta C^1/\delta t^1 + \mathbf{u}^1\nabla C^1 = \dfrac{D_a}{vL}\nabla^2 C^1$
Geometrically similar systems	
$qL/k\Delta T = f\left(Re, Pr, \dfrac{v^2}{JC\Delta T}\right)$	$NL/D_a\Delta C = f(Re, Sc)$

The enthalpy balance in B.T.U. for a solar still of area A containing W lb. of brackish water of enthalpy and G lb. of an air–water vapour mixture of enthalpy H_a is given by:

$$WH_w + GH_a = (I - B)At - H_cW_c \qquad (1)$$

where H_c is latent heat of condensation and W_c lb. of water are condensed on the canopy. Assuming $(I - B)$ is constant and differentiating (1):

$$W\mathrm{d}H_w + H_w\mathrm{d}W + G\mathrm{d}H_a = (I - B)At - H_c\mathrm{d}W_c \qquad (2)$$

Further operation on (2) is based on the definitions in Table 3.

Table 3

Enthalpy of water at T_w	$H_w = C_wT_w$
	$\mathrm{d}H_w = C_w\mathrm{d}T_w$
Humidity	$m_a = W_a/G$
	$\mathrm{d}W = \mathrm{d}w_a = G\mathrm{d}m_a$
Enthalpy of air–vapour mixture at T_a	$H_a = C_aT_a + m_a[H_m^{\circ} + C_w(T_a - 32^{\circ})]$
	$= C_aT_a + m_aH_v$
Humid heat	$H_s = C_a + C_w m_a$
Heat transfer	$GH_s\mathrm{d}T_a = h[T_w - T_a]\,A\mathrm{d}t$
Mass transfer	$GH_v\mathrm{d}m_a = k_a\,(P_w - P_a)\,H_vA\mathrm{d}t$
Bowen's ratio for open system (ref. 2)	$R = \dfrac{K}{LE} = 0{\cdot}46\left(\dfrac{T_w - T_a}{P_w - P_a}\right)\dfrac{P}{760}$

K, convection loss to air; L, latent heat evaporation; E, weight of water evaporated.

Applying the definitions in Table 3, it can be shown from equation (2) that:

$$W\Delta H_w + GH_v\mathrm{d}m_a\left[1 + \frac{h}{k_aH_v}\left(\frac{T_w - T_a}{P_w - P_a}\right)\right] = (I - B)At - H_c\Delta W_c \qquad (3)$$

Equation (3), when $\Delta W_c = 0$, may be compared with that for an open system given by Cummings in the nomenclature[3].

$$S + EL\left[1 + 0{\cdot}46\left(\frac{T_w - T_a}{P_w - P_a}\right)\frac{P}{760}\right] = (I - B) \qquad (4)$$

where S is the enthalpy of the water.

Using the heat/mass transfer ratio in Table 3, equation 3 can be simplified to:

$$W\Delta H_w = \left(\frac{M_a}{M_w}k_a P\right)\Delta H_a + (I - B)At - H_c\Delta W_c \qquad (5)$$

where ΔH_w, ΔH_a are the enthalpy changes in time t. From equation 5, if k_a is known, the weight of water evaporated can be estimated. The foregoing and similar enthalpy equations give evaporation-rates of the order obtained experimentally; it is, however, evident from Fig. 2 that equations based on a constant value of $(I - B)$ are only approximations.

The equation for linear conduction in an x-direction is:

$$\mathrm{d}T/\mathrm{d}t = \alpha\,\mathrm{d}^2T/\mathrm{d}x^2 \qquad (6)$$

If the temperature at a surface, $x = 0$, varies in a simple periodic manner:

$$T = T_0\sin\omega t = T_0\sin 2\pi t/P \qquad (7)$$

the solution of equation 6 for boundary condition 7 has the established form:

$$T = T_0\exp(-\mu x)\sin(\omega t - \mu x) \qquad (8)$$

where $\mu = \sqrt{(\omega/2\alpha)}$.

From equation (8), at a depth x, there will be a lag in the temperature wave of phase angle μx; this will amount to a complete period, and phase equality will be attained when $\mu x = 2\pi$ or

$$x = 2\sqrt{(\pi\alpha P)}$$

The solution may be put in the form:

$$\theta = T/T_0 = f(t/P, x/2\sqrt{(\pi\alpha P)}) \qquad (9)$$

which can be applied graphically.

Equations 8 and 9 apply to heat conduction through the Earth or solid material where the heat source is at the surface. In solar evaporation processes there is an absorption of radiation given by:

$$dI_\lambda/dx = -B_\lambda I_\lambda \qquad (10)$$

If the radiation energy is plotted against wavelengths for different depths, the total energy reaching a given depth can be estimated graphically. Evidently the results will depend on the physical and chemical properties of the absorbing medium.

Assuming that:

$$I_\lambda = f(\Delta T, k, \rho, c, L, \lambda, t, \mu) \qquad (11)$$

the results obtained by dimensional analysis are given in Table 4.

Table 4

$$I_\lambda L/\Delta T k = f(\mu c/k, \rho L \lambda/\mu t) \qquad (12)$$

Nusselt number	$N\mu_\lambda = IL/\Delta Tk = (I_\lambda k)/(\Delta T/L)$
Prandtl number	$Pr = \mu c/k = \nu/\alpha$
Modified Reynolds number	$(Re)_\lambda = \rho\lambda L/\mu t = (\rho v L/\mu)(\lambda/vt)$

Geometrically similar systems

$$N\mu_\lambda = f\,[Pr, Re(\lambda/vt)]$$

If, under some conditions, the group:

$$\nu/\alpha \leqslant (\rho v l/\mu)(\lambda/vt)$$

then absorption, at a given wave-length λ at a depth x, is given by:

$$I_{\lambda_0}\{1 - \exp(-B_\lambda x)\}$$

and may depend more on the ratio ρ/μ than on the thermal diffusivity α. Once the radiation is absorbed, and heat generated, conduction will proceed and thermal diffusivity predominate.

These considerations are of interest not only in enthalpy increases and evaporation but also in aqueous quantum processes which occur above a threshold frequency.

The voltage equivalent of the photons is given by:

$$V = hc/e\lambda \simeq 12400/\lambda\text{Å} \qquad (13)$$

Under normal conditions only a small fraction of the total photons may be effective. Also, back reactions reduce the conversion efficiency. If the reaction products could be removed and combined in some ingenious manner, electricity might be generated.

Water, for example, can be decomposed by radiation in the extreme ultra-violet and the electromotive force of the hydrogen–oxygen cell is given by:

$$E = \frac{RT}{zF}\left[\ln K - \ln \frac{C^2_{H_2O}}{C^2_{H_2}C_{O_2}} - \Sigma n_i\right] \qquad (14)$$

When evaporation in a solar still is prevented by a surface layer of inert oil, temperatures approaching 80° C. can be obtained; this may increase the quantum efficiency. In general, for reversible, isothermal processes at constant pressure:

$$zFE = \Delta A_T + \Sigma P_a dV_a = -\Delta G \qquad (15)$$

When $\Delta A_T = 0$ and if $P_1V_1 = P_2V_2$:

$$E = \frac{RT}{zF}\ln\frac{P_2}{P_1} \qquad (16)$$

where P may be a gas pressure or an osmotic pressure in an electrode amalgam.

Further:

$$F\,[E - T(\partial E/\partial T)] = \Delta H \qquad (17)$$

When ΔH (reaction) $= 0$

$$E = \text{constant} \times T \qquad (18)$$

If changes in concentration or pressure can be effected by absorption of solar radiation, the system may function as an engine converting heat into electricity.

In the foregoing and other connexions, solar stills, which can be instrumented for research, offer several interesting possibilities.

MOMENTUM SPECTRUM OF COSMIC RAYS AT SEA-LEVEL

By F. ASHTON, G. BROOKE, M. GARDENER, P. J. HAYMAN, D. G. JONES,
S. KISDNASAMY, J. L. LLOYD, F. E. TAYLOR, R. H. WEST
and A. W. WOLFENDALE

Department of Physics, The Durham Colleges in the University of Durham

PRELIMINARY results are given of the differential momentum spectrum of μ-mesons in the cosmic radiation at Durham (200 ft. above sea-level). The spectrum is used to make an estimate of the production spectrum of the parent π-mesons.

The measurements have been made with the Durham Cosmic-Ray Spectrograph, which consists of a large electromagnet ($\int H dl = 6{\cdot}2 \times 10^5$ gauss-cm.), with layers of Geiger counters and neon flash-tubes as the detecting elements. The overall height of the instrument is 4·95 m. and the aperture is ~ 20 sterad. cm.^2. The design of the instrument is based on the performance of a small prototype spectrograph, described by Ashton *et al.*[1]. The particle trajectories are traced through four measuring-levels, two placed above and two below the magnet. At each level there is a layer of Geiger counters, each counter being attached to an electronic unit giving pulses characteristic of its position in the layer, and eight close layers of neon flash-tubes. The flash-tubes give a precise indication of the position of a particle accepted by the counter selection system.

The measurements at low momenta have been made with the Geiger counter arrangement alone; an electronic momentum analyser computing the deflexion of each particle from the pulses arriving from the counter units at each level. Some 160,000 particles with momenta greater than 1 GeV./c. have been recorded so far. Corrections have been made for the small flux of protons using the proton spectrum measured by Mylroi and Wilson[2], and the resulting μ-meson spectrum is shown in Fig. 1. Only comparative rates are determined and the flux is normalized to that given by Rossi[3] at

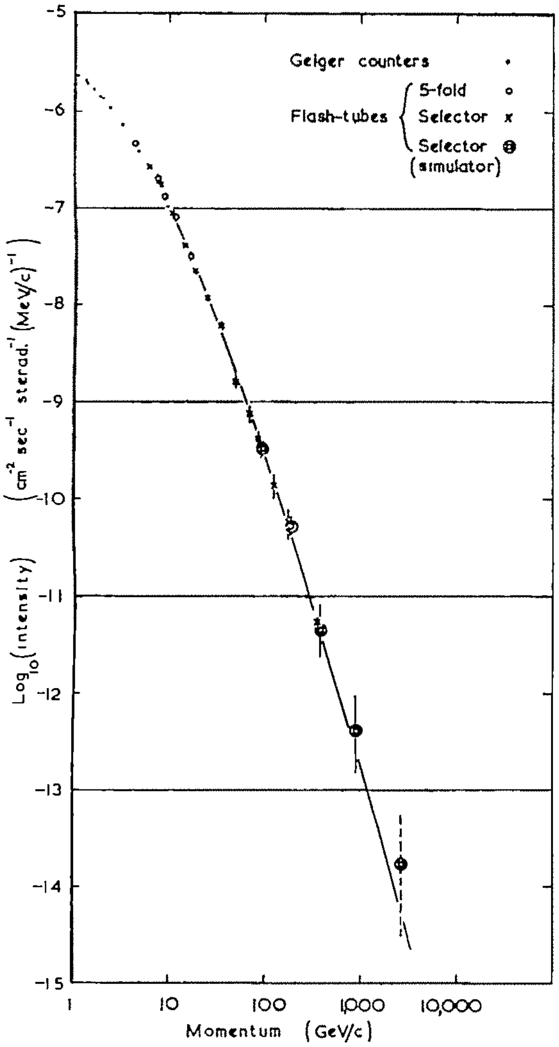

Fig. 1. Differential spectrum of μ-mesons at Durham (200 ft. above sea-level), based on measurements of about 164,000 particles, of which 80 had momenta greater than 100 GeV./c.

1 GeV./c., that is, $2{\cdot}45 \times 10^{-6}$ cm.$^{-2}$ sec.$^{-1}$ sterad.$^{-1}$ (MeV./c.)$^{-1}$.

The measurements have been extended to higher momenta using the arrays of flash-tubes. In order to check the reliability of this technique, a series of photographs has been taken in which the flash-tubes are operated for every particle accepted by the counter system. The measurements are shown in Fig. 1, where they are designated '5-fold' data. The experimental points below 4 GeV./c. have been omitted for clarity. The results are clearly consistent with the counter data.

For good statistical accuracy at higher momenta some selection of particles is required; this is performed by operating the momentum analyser in conjunction with a momentum selector which produces an output pulse only for particles undergoing small deflexions in the spectrograph. Measurements on the flash-tube photographs, made with moderate accuracy using a re-projection system, are sufficient for momenta up to several hundred GeV./c. (designated 'Selector' data in Fig. 1). At still higher momenta a more accurate method is required, and a track simulator is used. With this device a detailed study is made of each track at each level, using the information on track location given by both flashed and unflashed tubes. The maximum detectable momentum of the instrument is (1,000 ± 200) GeV./c. for measurements made in this way; this being the momentum corresponding to a deflexion equal to the probable error of the deflexion measurements. Such results are designated 'Selector (simulator)' in Fig. 1.

Comparison has been made with various other spectra. Below 20 GeV./c. the spectrum is consistent with the results of Owen and Wilson[4] and Caro *et al.*[5]. Between 20 GeV./c. and 200 GeV./c. there is agreement with the spectra of Pine *et al.*[6] and Holmes, Owen, Rodgers and Wilson[7], but not with that of Caro *et al.*[5].

The form of the production spectrum of the π-mesons, whose decay gives rise to the μ-mesons, is an important derivation from the sea-level μ-meson spectrum. Puppi[8] has derived the exponent of the π-meson production spectrum, γ, using the earlier sea-level spectra, with the result that γ is about $2{\cdot}47$ over the range 1–10 GeV./c. and increases slightly at higher energies. Our result is consistent with this conclusion.

Above 20 GeV./c. the exponent has been derived from the analysis of Barrett *et al.*[9]. Using simplifying assumptions, these workers show that a π-meson production spectrum of exponent γ gives rise to a sea-level differential μ-meson spectrum of the form $N(p) \propto \dfrac{1}{p^{\gamma}} \left(\dfrac{1}{1 + p/90}\right)$ (with p in GeV./c.). We have corrected this relation for the momentum loss of μ-mesons in the atmosphere and loss by μ–e decay, and compared it with the experimental results for various values of γ. The exponent giving the best fit is $\gamma = 2{\cdot}55$, and the spectrum using this exponent is shown as the full line in Fig. 1. The conclusion to be drawn from the study of the π-meson production spectrum is that there is little change in the exponent over the range 1–500 GeV./c. This conclusion is of interest in connexion with the high exponent ($\gamma \sim 4{\cdot}3$) inferred from the work on γ-ray cascades reported by Duthie *et al.*[10].

The slope of the sea-level μ-meson spectrum increases continuously with momentum, reaching a value of $-3{\cdot}2$ over the range 100–1,000 GeV./c.

A fuller account of the present work will be published elsewhere.

We thank Prof. G. D. Rochester for his encouragement and interest in all stages of the work.

Grateful acknowledgement is made to the Department of Scientific and Industrial Research for the award of several Special Research Grants and Studentships. Thanks are also due to Profs. P. M. S. Blackett, S. Devons and J. G. Wilson, for their co-operation in making available the large electromagnet.

DETERMINATION OF STRONTIUM-90 DISTRIBUTION IN HUMAN BONE

By R. BJÖRNERSTEDT and S. HÄGGROTH
Research Institute of National Defence, 4th Division, Stockholm 80

THE level of strontium-90 in human bone as a result of fall-out has been determined by Kulp *et al.*[1] to be 0·19 μμc./gm. calcium (S.U.) as of January 1958. This value is a world average for adult skeletons. If data for children are included, the average value becomes 0·52 S.U., but there is a variation of the strontium concentration with age, giving a maximum at about 1 year of 1·5 S.U. These levels change with time, however, and Kulp estimates that a maximum concentration in young children will occur at about 1966, on the average corresponding to 4 S.U. and none exceeding 80 S.U. (assuming no further testing).

For an evaluation of the possible biological effects of the strontium burdens cited, it may be of importance to know the distribution of strontium-90 inside the skeleton[2]. From what is known about the metabolism of strontium in bone it is to be expected that the unevenness of the distribution should vary with age and date of birth[3]. For children born after 1954 one would, for example, expect a fairly diffuse and uniform labelling of the bone, while, on the other hand, for individuals born in 1934 or earlier some diffuse and some 'hot-spot' labelling should occur. From, for example, the work of Schulert *et al.*[4] it is evident that an uneven distribution does, in fact, occur if the strontium-90 activity of different bones or different parts of the same bone are compared. The existence at present of hot spots in human bone has, however, not been proved or disproved directly. This would most readily be done with an autoradiographic technique, but the present strontium-90 levels in human bone have been considered too low for this technique to be useful. This assumption will be discussed here. If strontium-90 in bone (varying between 0·1–100 S.U. for different individuals and at different times) is to be studied autoradiographically it is necessary to consider what other activities may be found in bone. For comparison, 1 S.U. corresponds to 0·31 betas/min./gm. of bone from strontium-90 (0·55 MeV.) and the same number from yttrium-90 (2·26 MeV.).

Of the naturally occurring radioisotopes, potassium-40 dominates. 880 p.p.m. potassium in bone[5] gives 1·53 betas/min./gm. bone. Carbon-14 gives 3·2 betas/min./gm. bone[3], but with a maximum energy of only 155 keV. against 1·3 MeV. for potassium-40. Radium-226 is present in small amounts, a body burden of 10^{-10} gm. giving about 0·07 alpha and 0·05 beta/min./gm. bone. Bone may contain other activities besides strontium-90 from fall-out. At present, when no new nuclear weapons tests have been carried out for more than a year, only cæsium-137 could compete. A value of around 0·13 beta/min./gm. bone is to be expected.

If a thick bone sample is autoradiographed, the activities mentioned will have the following importance in approximate relation to 1 S.U. strontium-90: strontium-90, 1·0 by definition; potassium-40, 2·3; radium-226, 1·2; carbon-14, 0·5; and cæsium-137, 0·08. This is comparing the dosages at the surface of a thick bone sample. The maximum ranges of carbon-14 betas and radium-226 alphas are only 100μ and 35μ, respectively, however, and so these contributions may be excluded if a thin absorber is used between the bone sample and the film emulsion. It is still apparent, though, that a study of the present levels of strontium-90 (0·1–2 S.U.) is made difficult by the presence of potassium-40 in bone. This difficulty should, however, be less important in the future if the predicted increase of the strontium-90 levels is found.

In order to avoid disturbances from other activities than strontium-90 and yttrium-90, a new technique of sample preparation has been tried. When a sample of fresh human bone is ashed at a temperature of 700–800° C. it is found that the geometry of the sample changes very little. A section of, for example, the femur, some millimetres thick, becomes slightly twisted and shrunken, but the essential dimensions are almost unchanged. This is true as well for areas of trabecular bone. Using highly active animal bone, we have found that the process of ashing does not change the strontium distribution to any noticeable extent. Hot spots that existed before ashing are still found afterwards and no new concentrations have been created. From what is known about the structure of bone one would expect the geometrical distributions of strontium in fresh and ashed bone to be identical if the bone keeps its geometry during ashing.

The bone sample is white after the ashing, all organic material and particularly carbon (and thus carbon-14) having vanished. The content of potassium-40 has been determined by γ-spectrometry on a 500-gm. femur ash sample. (We are indebted to Mrs. K. Low for making the measurements.) The result was 430 ± 120 p.p.m. potassium in bone ash, which corresponds to 180 ± 50 p.p.m. in fresh bone. This value is only 20 per cent of that in ref. 5. The difference may perhaps be explained by variations in the preparation of the bone before ashing. In our case, as much as possible of the organic material was removed beforehand. The sample measured was too small to demonstrate the presence of any cæsium-137.

The low value found for potassium-40 in bone ash reduces the effect on the determination of strontium-90 discussed previously from 2·3 to less than 0·5 (strontium-90 = 1·0). A still further reduction may be achieved if the ashed bone sample is carefully soaked and washed with water or ammonium carbonate solution. In this way, 570 p.p.m. of potassium-40, that is, between 90 and 100 per cent, has been extracted from the above-mentioned femur sample. The same is most probably true for cæsium-137 as well, although it has not been possible to check this as yet. A similar extraction carried out on highly active (strontium-90) animal bone revealed that only a small fraction (1–2 per cent) of the strontium is removed in the process. This should apply to radium-226 as well. It is thus possible to prepare bone samples which contain almost only strontium-90 + yttrium-90 and radium-226 activity (for 1 S.U.: strontium-90 = 1·0; radium-226 ~ 1·2; potassium-40 < 0·05; cæsium-137 < 0·01; and carbon-14 ~ 0).

One might now ask what times of exposure are necessary to produce an autoradiograph of these low levels of strontium-90. 1 S.U. corresponds to about 1 beta/cm.^{2}/hr. on the surface of a sample of bone[6]. Using X-ray film ('Kodirex') it has been reported[7] that a good autoradiogram is produced in 80 days with a bone sample containing not more and probably less than 126 S.U. In about the same time 'a very slight image' was produced with a sample containing not more than 11 S.U. Similar results have been obtained in our laboratory. These exposures should correspond to about 250,000 and 25,000 betas/cm.^{2}, respectively. It is interesting to note that the hard cosmic-ray component would in an 80-day exposure contribute about 120,000 tracks/cm.^{2} of emulsion. To make possible autoradiographs on the 1 S.U. level this high background must be reduced. A factor of 10 may, however, be gained through storage in a shelter with a 20-m. rock roof. Additional lead shielding of the films is then required to absorb the γ-radiation from both the rock itself and from radon with daughter products. In this way, a film background over 80 days of less than 10,000 tracks/cm.^{2} should be a possibility.

In addition to this it would be necessary to reduce the thermal and chemical blackening that takes place during storage and which over a year may increase from, for example, 0·06 to 0·30 (ref. 8). A twofold reduction of this blackening results if the film is stored at low temperature (between − 5° C. and + 5° C.). The blackening due to carbon-14 and tritium in the emulsion, finally, is negligible in comparison with the cosmic ray background.

Granted that underground cold-storage is effective in reducing the background blackening of X-ray films, it is reasonable that 100,000 betas/cm.^{2} should produce a good autoradiogram and 10,000 betas/cm.^{2} a very slight one on 'Kodirex' film. For 1 S.U. this corresponds to exposure times from about 10 and 1 years, respectively. Comparing 'Kodirex' with other X-ray films, the following figures for relative speed may be cited[8]: 'Kodirex', 35; '*CEA* Textur-*X*', 47; 'Ilfex', 52; Ilford Industrial *G*, 57; Kodak Industrial *K*, 77; and Fuji Industrial 200, 100. Up to a factor of 2–3 in exposure time may thus be saved using films that have high speed. Additional time may possibly be saved if local strontium-90 concentrations occur.

A second way to use autoradiography to study the labelling of human bone with strontium-90 is with β-sensitive nuclear emulsions. To begin with, the emulsion would have to be cleaned from the existing background of β-tracks. This is possible with a water-vapour treatment for some hours at 50–60° C.[10]. Subsequent exposure to attain 10^3–10^4 betas/cm.^{2} may produce results that are measurable by microscopic scanning[11].

It may thus be possible, using an exposure time of one year, to get a weak autoradiogram of bone carrying 1 S.U. diffusely distributed. This type of distribution corresponds to that of bones from children younger than fifteen years (0·7–1·5 S.U.). For adults having an average of 0·19 S.U. (January 1958) it is to be expected that local concentrations will occur, some parts of the bone containing strontium-90 in excess of 1 S.U. This should again be observable with exposure times of about a year. An increase of the future strontium-levels would make the autoradiographic method still more feasible.

POTATO WART DISEASE, *SYNCHYTRIUM ENDOBIOTICUM* (SCHILB.) PERC.

By VÍT BOJŇANSKÝ

Plant Protection Laboratory, Ivanka pri Dunaji, Czechoslovakia

IT was thought in the past that the potato wart fungus could exist equally well in cold as in warm or even sub-tropical regions, that is, in all places where potatoes[1,2] are cultivated. This opinion diverted attention from the investigation of ecological factors affecting the fungus in its environment. Uncertainty about this led me to a detailed study of the genesis and disappearance of the first occurrence of potato wart disease in Europe[3,4], to the laying down of field tests in sub-arid and arid regions, and to the utilization of data about the historical and present occurrence of potato wart disease throughout Europe.

Analysis of the climatic conditions of the district of Hornany in Czechoslovakia, where potato wart disease was first described[4], shows that the disease ceased to exist after a drier and warmer period[3].

Field tests in the sub-arid region of Czechoslovakia showed that among tubers harvested in humid regions from land in an area where there had been a marked appearance of potato wart disease no case of the disease was found. However, when every potato plant was given 5 kgm. of totally infected soil from the humid area where the Wohltmann variety crop was 90–95 per cent destroyed, a small amount of wart disease was registered in the first year, a smaller amount in the second year, and little or nothing in the third year (Fig. 1). Very often the out-growths were atypical. When in the period 1951–58 the gradually infected soil was brought back from the sub-arid region to a humid area (5 kgm. of totally infected soil for each potato plant) the appearance of wart disease was detected as shown in Fig. 2. It was also found that when totally infected soil from the humid area was placed in the sub-arid region without being mixed with the soil of that region the amount of wart disease was greater, and the cleansing of the soil from the fungus slower. In the fourth year the disease was sporadic or lacking. In the humid area in the same soil wart disease was proportionately greater (Fig. 3).

Judged from the results obtained, the practical eradication of the potato wart fungus from the soil in sub-arid regions does not take long even when the soil is strongly infected (2–3 years), though complete eradication takes longer (5–7 years) and this happens even when non-immune varieties of potatoes are grown.

Analysis of the occurrence of wart disease in European States from the climatological–geographical point of view demonstrated that the greatest intensity is in the mountainous and sub-mountainous regions of central, northern and eastern Europe. In the maritime countries by the North Sea (Great Britain, Benelux, Northern France) there is a smaller and economically less significant amount, however humid and mild the climate. In the warmer regions of southern Europe, and the sub-arid plains of central Europe having a continental climate, wart disease has not been reported.

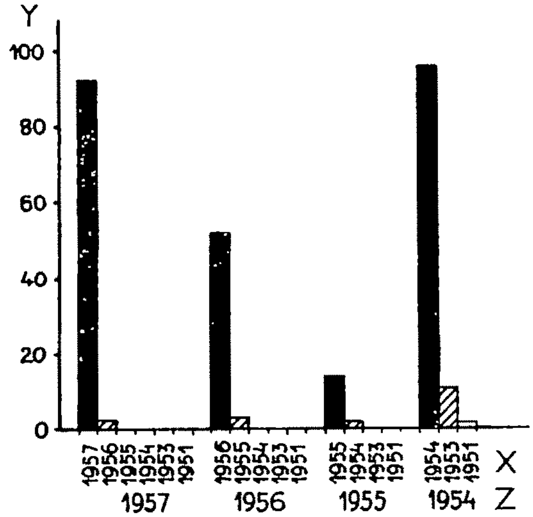

Fig. 1. Intensity of wart disease in sub-arid regions on soil highly infected (5 kgm. totally infected soil from the humid area to each potato plant). *X* = year of infestation of the soil; *Y* = weight of outgrowths in gm.; *Z* = year of the experiment

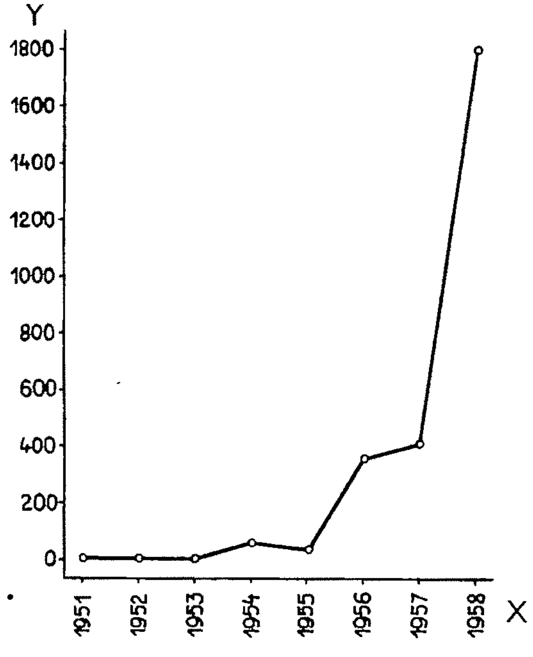

Fig. 2. Intensity of wart disease in the soil gradually infested (5 kgm. totally infested soil to one potato plant) in the sub-arid region in 1951–58 and in 1958 brought into humid region. *X* = year of infestation of the soil; *Y* = weight of outgrowths in gm.

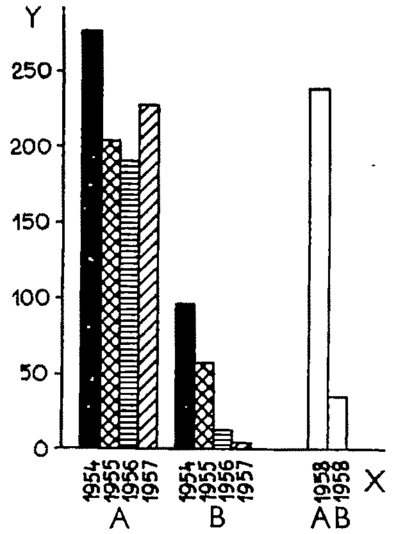

Fig. 3. Intensity of wart disease in totally infected soil, placed in 1954 in the humid *A* and sub-arid *B* regions and in 1958 returned to the humid region. *X* = year of experiment, *Y* = weight of outgrowths in gm.

Temperature and rainfall, and to a certain extent the nature of the soil, are the most decisive factors in the successful or unsuccessful development of the fungus.

The potato wart fungus likes climates which may be characterized thus: low summer temperature (under 18° C.), long and deep winters (160 and more days with temperatures below 5° C.), heavy precipitation (700–800 mm. and more per annum, the greater part during the summer), sufficiently aerated and extensively cultivated soil, with an acid reaction and poor rotation of crops, where potatoes are planted every second or third year. In areas with mild, short winters many zoosporangia germinate without infection taking place. Rapid cleaning of the soil follows, and the appearance of wart disease is sporadic or nil and economically of no importance.

The results of the investigations have made it possible, first, to establish for Europe a prognosis of the occurrence of potato wart disease, according to which suitable, less suitable, and unsuitable zones can be fixed for the contamination and development of potato wart disease; secondly, to regulate the breeding and cultivation of potatoes. In the unsuitable zone it is possible without apprehension to cultivate non-immune varieties of potatoes, many of which are more tolerant to degeneration and important from the point of view of production of early potatoes. Finally, it is possible to solve plant quarantine questions, and control the disease according to the individual ecological–geographical zones.

Further details will be given in my book, "Ecology and Prognosis of Potato Wart Disease", to be published with an extensive English summary by the Slovak Academy of Sciences Press in 1960.

PHYSICS

Self-quenching Geiger Counters containing Mixtures of Permanent Gases

We have investigated the characteristics of Geiger–Müller counters containing mixtures of argon with small quantities of xenon (0–7 per cent), oxygen (0–0·5 per cent) and nitrogen (~ 1 per cent), to total pressures of 700 mm. mercury. That counters filled with this mixture would behave as 'fast' counters in a manner similar to organically quenched counters was first reported by Shore[1], although Riedel[2] reported that using the filling recommended by Shore produced no Geiger region. Using counters of the conventional 'gamma' type, glass bodies with cylindrical cathodes of various materials together with a 4·7 megohm series resistor and a linear amplifier of a gain of about 25, we find that optimum proportions of the gas mixture to produce the best plateaux are: xenon (3·5 per cent), oxygen (0·3 per cent), nitrogen (1·2 per cent), with argon added to give a total pressure of 700 mm. mercury. Such a mixture gave a plateau about 170 V. in length, with a starting voltage of 1,460 V. and a plateau slope of 0·02 per cent/V.

Some fairly general conclusions can be reached as to the role of the various components in the mixture in producing the Geiger plateau. It is evident that the oxygen makes possible the rapid spread of the discharge along the counter anode, chiefly by photoionization, in the manner described by Huber[3]. This was made clear when fillings of pure argon and argon plus 1 per cent xenon were investigated, by examination of the discharge by oscilloscope. It was found that with both these mixtures there was no Geiger region, the discharge passing abruptly from the proportional to the corona region, the voltage at which this occurred being lowered from 1,850 V. to 1,260 V. with the addition of xenon. Addition of 0·1 per cent of oxygen to pure argon altered the character of the discharge entirely, the familiar Geiger pulses being observed although a plateau of only a few volts was obtained with many spurious pulses.

Although Shore reported that, if nitrogen were not present in the mixture, the plateau became extremely short, we have not found this to be so. The addition of about 1 per cent of nitrogen improves the performance of the counters but is not essential. For example, a counter containing the optimum quantities of xenon and oxygen had a plateau of 102 V. in length with a slope of 0 064 per cent/V. Refilling and adding 1 per cent of nitrogen resulted in an increase in length to 130 V. and the slope improved to 0·025 per cent/V.

It is also clear that the presence of the xenon inhibits the formation of the many spurious pulses found in the argon–oxygen–nitrogen mixtures. Adding small quantities of xenon to the latter results in an improvement in length and slope of the plateau together with a very sharp fall in the starting voltage, from 2,124 V. for zero quantity to 1,460 V. for the optimum amount of xenon (3·5 per cent). Adding further xenon results in an increase in the starting voltage, and a deterioration of the slopes and lengths of plateaux.

In an endeavour to understand this mechanism we have investigated the time incidence of spurious pulses by pulse-interval analysis[4] for mixtures containing increasing quantities of xenon with fixed amounts of nitrogen (1 per cent) and oxygen (0·3 per cent). At the same time we have measured the transit times of the front of the positive-ion sheath from examination of the cathode-current pulse. In all the many fillings investigated we have found that the maximum number of spurious pulses occur at the end of the counter dead-time and only a negligible proportion are recorded after the front of the positive-ion sheath has reached the cathode. It is apparent, at any rate with these counters, that the positive-ion effect at the cathode, often quoted as the reason for the generation of spurious pulses in Geiger counters, is unimportant.

The other possible mechanism is that the spurious pulses are due to hard photons, delayed relative to the main Geiger pulse, releasing photo-electrons at the cathode. Such hard photons could arise as a result of the quenching of argon metastables by collision with gas molecules. In fact, pulse-interval analysis of mixtures containing zero or less than optimum quantities of xenon shows large numbers of small spurious pulses occurring in as short a time as 15 μsec. after the main Geiger discharge. With optimum quantities of xenon such small pulses do not appear and the counters have a clear dead-time of about 150 μsec, indicating that the argon metastable states are rapidly quenched by collisions with xenon atoms. That this occurs, and with the formation of ions, is also indicated from the considerable lowering of starting voltage with addition of xenon, while the charge per pulse remains of the same order. The ionization potential of xenon (12·127 V.) is higher than both metastable levels of argon (11·53, 11·72 V.) so that direct ionization of xenon atoms by collision with argon metastable states is not possible; but in spite of this it seems fairly evident that some mechanism exists involving interaction between xenon atoms and argon metastable states giving rise to an increase in the number of ions produced in the avalanches.

A more detailed report of the work described in this communication is to be published elsewhere.

An Image Intensifier with Transmitted Secondary Electron Multiplication

THE use of transmitted secondary electron emission for electron multiplication has been proposed by Lubszynski[1], McGee[2] and Sternglass[3], and photoemissive image intensifiers incorporating thin films of potassium chloride as transmitted secondary emitters have been described by Wachtel, Doughty and Anderson[4]. We also have been experimenting with the construction of image intensifiers of this kind.

The form of the tubes we have made is shown in Fig. 1. They consist essentially of an antimony–cæsium photocathode, an aluminium-backed zinc sulphide–silver phosphor, and between these a set of parallel electron-multiplying dynodes which are layers of aluminium and potassium chloride deposited on a supporting film of aluminium oxide. Electrons from the photocathode are accelerated and focused on the first dynode by means of coaxial electric and magnetic fields, and secondary electrons are produced which escape from the dynode on the side remote from the photocathode. These transmitted secondaries are similarly accelerated and focused on the second dynode, where further transmitted secondary electrons are produced; and this process is repeated down the tube. Finally, the electrons which emerge from the last dynode are accelerated and focused on the phosphor.

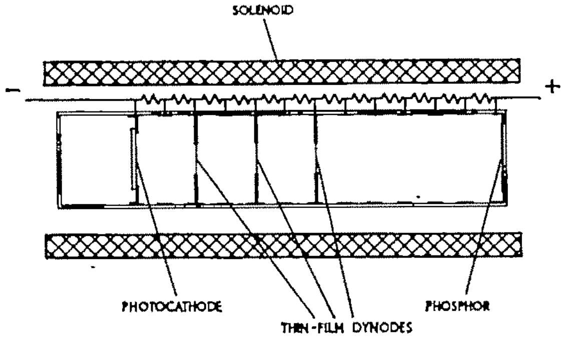

Fig. 1. Image intensifier with transmitted secondary electron multiplication

The electric field is provided by cylindrical electrodes on the inner wall of the tube, which are connected to an external potential divider. The magnetic field is provided by a long solenoid which surrounds the tube. In order to prepare the photocathode without admitting cæsium to the working section of the tube we have made use of the arrangement described by McGee[5]. At a short distance from the front window of the tube there is an annular metal shelf which fits the inside of the tube closely enough to act as a barrier to cæsium vapour, and a glass plate is held to this shelf by means of a spring catch which can be released by tapping the outside of the tube. The photocathode is formed on the surface of the plate which faces the front window of the tube. After the tube is sealed off from the pumps, the plate is released and turned over so that the photocathode faces the dynode system.

The tube we have prepared most recently has five 1-cm. diameter dynodes, each consisting of a layer of aluminium ~200 A. thick and a layer of potassium chloride ~500 A. thick deposited on a film of aluminium oxide ~450 A. thick. The sensitivity of the photocathode is 20 μamp./lumen. We have operated this tube with 37 kV. between photocathode and phosphor. The potential difference between the cathode and the first dynode, and between successive dynodes, is then about 4·9 kV., and the magnetic field required for focus is 180 gauss. Under these conditions the total electron multiplication is $\sim 3\cdot5\times10^{3}$, and the ratio of total light output to light input is $\sim 8\times10^{4}$ when the incident light is of the same mean wave-length as the phosphor emission. The sensitivity of the photocathode corresponds to a quantum efficiency of about 4 per cent at this wave-length, so that each electron leaving the cathode must result on average in a pulse of about 2×10^{6} photons from the phosphor. These pulses are easily visible

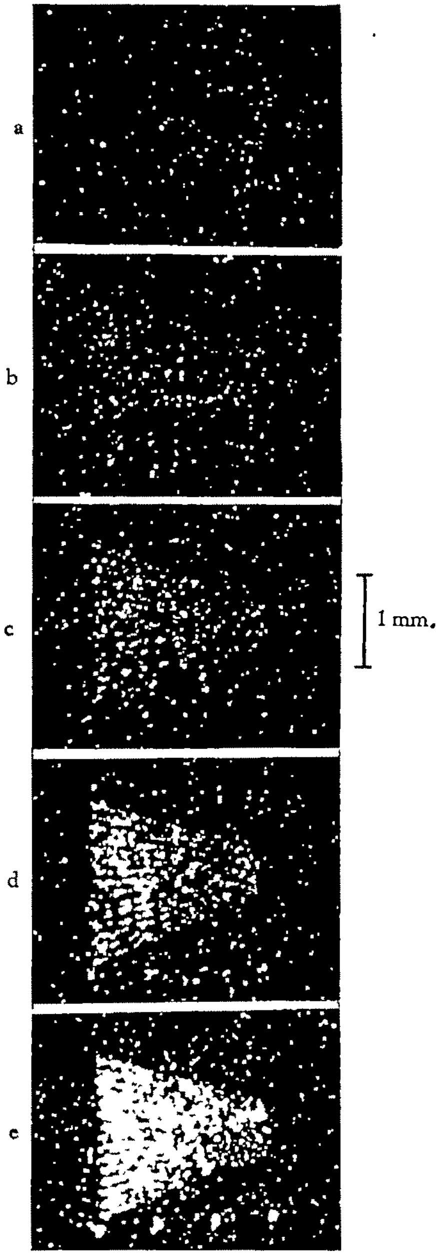

Fig. 2. Photographs obtained with image intensifier showing scintillations resulting from single electrons leaving the photocathode: *a*, dark background; *b*, *c*, *d*, *e*, image of fan-shaped test object projected on photocathode with successively increased levels of illumination. Exposure times 0·5 sec.

with a low-power microscope as bright scintillations on the phosphor, with diameters of about 40 microns. For an average scintillation the photon density at the phosphor thus exceeds 10^{11} photons cm.$^{-2}$, and since a photon density of 10^{8} photons cm.$^{-2}$ is sufficient to give a detectable image on a very fast photographic emulsion[6], it is to be expected that the scintillations can be photographed with relatively inefficient optical coupling between the phosphor and the emulsion.

We have been able to take such photographs (Fig. 2) on Kodak Tri-*X* film, using a pair of 50 mm. *f*/2 lenses front-to-front to give unity magnification. The exposure time for each photograph was 0·5 sec. Fig. *2a* was taken with the tube in the dark at room temperature, and shows the scintillations due to dark emission from the photocathode. The rate of background scintillation is $\sim 6 \times 10^{3}$ cm.$^{-2}$ sec.$^{-1}$. The corresponding cathode dark current, if each electron emitted gives rise to a scintillation, is $\sim 10^{-15}$ amp. cm.$^{-2}$, which is a reasonable value for an antimony–cæsium cathode. For Figs. *2b*, *c*, *d* and *e*, the image of a resolution test object was projected on to the photocathode with successively increased levels of illumination. The test object was a fan of 15 black-and-white line-pairs. In Fig. *2b* the illumination is so low that the photo-emission is only of the same order as the dark emission, and the object is detectable only as a local increase in the scintillation density. Increases in illumination lead to the object becoming barely recognizable (Fig. *2c*), and clearly so (Figs. *2d*, *e*). The limiting resolution is about 15 line-pairs per mm., and is determined largely by the diameters of the scintillations.

We are grateful to Prof. J. D. McGee for his interest and encouragement, and to the Department of Scientific and Industrial Research for financial support.

Ultrasonic Velocities in Aqueous Solutions of Cadmium Iodide and Mercuric Chloride

In the course of a systematic study of the ultrasonic behaviour of aqueous solutions of inorganic salts, I have come across two cases (mercuric chloride and cadmium iodide) which behave in a peculiar manner. Preliminary measurements on the velocity of ultrasonic waves in aqueous solutions of the above salts have been made using a variable path interferometer working at 750 kc./sec. An accuracy of 0·15 per cent is obtained. The results are presented graphically in Fig. 1.

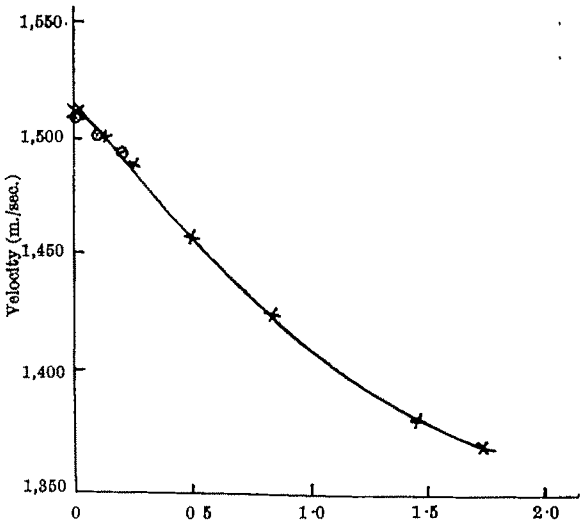

Fig. 1. ×, cadmium iodide; ○, mercuric chloride

In contrast with the normal behaviour of electrolytes, ultrasonic velocities of these solutions decrease with increasing concentration. Cadmium iodide registers a large decrease. Ultrasonic velocity at a concentration of 1·75 *M* is 1,369 m./sec., resulting in a lowering of 140 m./sec. from the value for pure water. Mercuric chloride shows a relatively smaller change, the velocity in its 0·25 *M* solution being 1,489 m./sec.—a lowering of 18 m./sec. Even though the ultrasonic velocities decrease with increasing concentration, the adiabatic compressibility decreases with increase of concentration. Full details of this investigation will be published shortly.

I am indebted to Dr. J. Bhimasenachar for his encouragement and helpful discussions during the course of this work.

A Sidewall Friction Effect during Soil Consolidation

In the course of investigating the consolidation properties of a sensitive marine clay, a variety of consolidation test procedures has been used. Some followed normal incremental loading procedure, but with widely varying increment ratios. Other tests employed continuous loading techniques either by straining the specimen at a constant rate or by applying load at a constant rate.

When the specimens were oven dried after test, an unusual phenomenon was observed. Specimens that had been subjected to incremental loading revealed a dark ring of soil at mid-height around the perimeter. During the drying this ring of soil appeared to shrink more than the rest of the specimen; it often fell away leaving a spool-shaped specimen as shown in Fig. 1. The phenomenon was never observed on specimens subjected to continuous loading.

In a paper[1] which describes this work more fully, it is reasoned that the differential shrinkage in specimens loaded in increments is a manifestation of unequal stress distribution across the specimen and that sidewall friction between specimen and enclosing ring is the primary cause of the non-uniformity. Reference to probable effective stresses through incrementally loaded specimens suggests that unequal consolidation will occur, but that in continuous

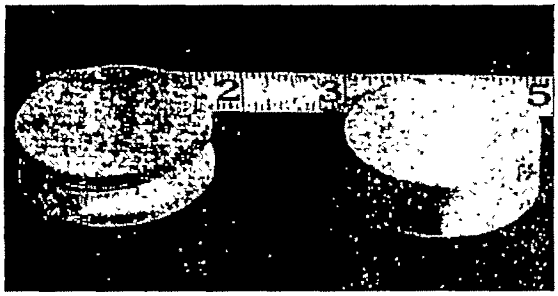

Fig. 1. Differential shrinkage of oven-dried sample due to unequal stress distribution. Specimen on left subjected to incremental loading $\Delta p/p = 1$; specimen on right tested by a continuous load increase technique

loading tests (pore water pressure assumed to be zero) a more uniform consolidation is visualized. This appears to have an important effect on the measured preconsolidation pressure. Although the phenomenon reported was observed in a highly compressible, sensitive clay it may be found in other soils.

METALLURGY

Interstitials and Fracture of Metals

INTERSTITIAL alloying elements, even in minute quantities, exert a potent influence on the mechanical behaviour of alloys. Of particular recent interest has been the behaviour of hydrogen in steels; where the phenomenon of hydrogen-induced delayed brittle failure has received special attention[1–3]. Time-dependent brittle failure implies that spontaneous brittle fracture will occur at loads substantially below those that may have been previously successfully sustained. The characteristic features are: (*a*) an incubation period; (*b*) slow crack propagation; (*c*) a lower critical stress below which failure will not occur. Both the incubation period for crack initiation and crack growth are controlled and paced by the diffusion of hydrogen[4–6,8].

The incubation period depends on the time required to accumulate a critical concentration of hydrogen in the region of maximum triaxiality. Diffusion to this region is induced by the strain gradient associated with the inhomogeneous stress field, wherein the strain gradient acts as an activity gradient or driving force. It has been demonstrated recently[9] that the attainment of the critical hydrogen concentration is determined by the magnitude of the applied stress. That is, the applied stress governs the magnitude of the strain gradient. High triaxial stress states are brought about by notches. The notches may be artificial (excavated), inherent (inclusions, grain boundary intersections, dislocation arrays, etc.) or combinations of these. However, when brittle fracture is involved, modern theory requires one of the effective notches to be a dislocation array. Therefore, coupled with the strain gradient of an artificial notch may be an additional driving force associated with a dislocation array at the base of the notch. All this suggests that there are two criteria for delayed brittle failure; specifically, a critical concentration of hydrogen and a critical stress state. These two criteria are the basis of the discontinuous nature of crack propagation which is a unique characteristic of this type of time-dependent brittle failure.

The occurrence of discontinuous crack propagation makes it difficult to rationalize delayed brittle failure by applying any mechanism which postulates raising the flow stress to the fracture strength. On the other hand, a decrease in the cohesive strength of the lattice provides a ready explanation for this phenomenon. This could be brought about by localized concentration of interstitial atoms in the region of the critical stress state in the form of an uncondensed atmosphere[10]. Probably a more general situation would be one which involves both a rise in flow stress brought about by plastic deformation and a lowering of the cohesive strength. Presumably the proportions of these two could vary over a wide range.

Once the crack has been initiated, it will be propagated until it exceeds the radius of influence of the accumulated interstitials. Beyond this point the moving crack will be damped out rapidly due to plastic flow ahead of the crack. Another incubation period is then required to build up the critical concentration at the tip of the crack. This step-like process continues until the effective area is reduced such that the applied stress is equal to the notched strength of the material. Thus, a lion's share of the time to failure resides in the sum of the successive incubation periods.

No restrictions are apparent which limit this behaviour to hydrogen and steel. Indeed, the only restrictions to a general behaviour of this type are that a critical stress state exists and that the interstitials have sufficient mobility to attain a critical concentration in a reasonable length of time. Hence, one may well anticipate that any interstitial in any metal which can accommodate the critical stress state may induce delayed brittle failure.

A major step in evaluating this concept involved an examination of the particular case of carbon (nitrogen) in steel. In the temperature-range 700–1,000° F. carbon has approximately the same mobility

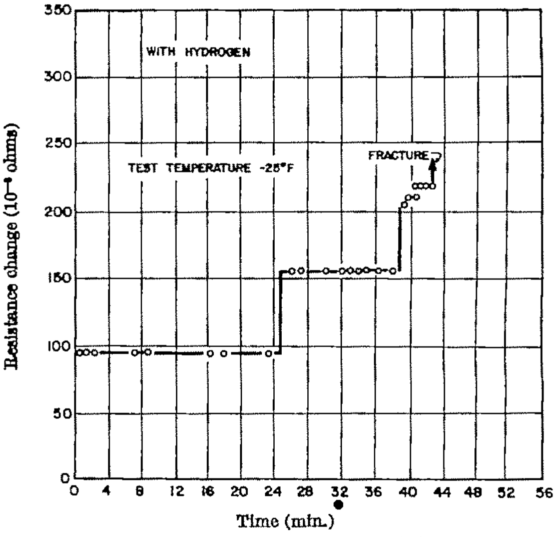

Fig. 1. Resistance vs. time in the delayed-failure stress range of a uniformly hydrogenated nickel–chromium–molybdenum steel

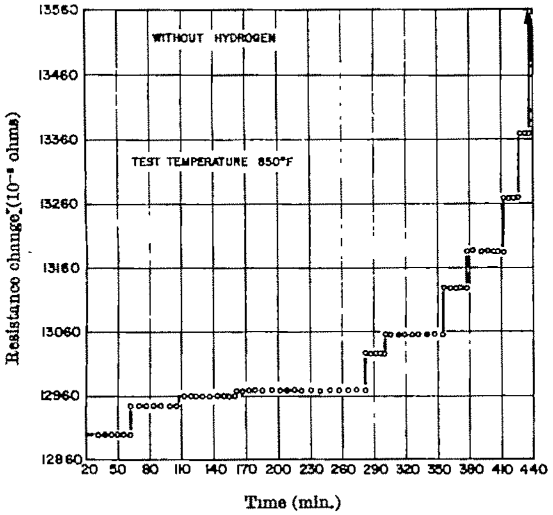

Fig. 2. Resistance vs. time in the delayed-failure stress range of a high-temperature die steel

in steel as has hydrogen at room temperature. Notched specimens of a high-temperature die steel (0·40 per cent carbon, 0·35 per cent manganese, 1·10 per cent silicon, 5·00 per cent chromium, 0·90 per cent vanadium, 1·35 per cent molybdenum) were subject to sustained-load-to-failure tests in the appropriate temperature-range. Resistance versus time measurements[3,4] were recorded during the sustained-load tests. All the significant features of time-dependent brittle failure were observed in an almost perfect image of the behaviour of hydrogen in steel (cf. Figs. 1 and 2). Fig. 2 vividly illustrates the incubation period and the step-like appearance associated with discontinuous crack propagation.

These results lend authority to the concept that interstitial-induced delayed brittle failure may be a general behaviour in metals which can attain the critical stress state in the temperature-range dictated by the mobility requirement. The implications derived from this work are far-reaching. They indicate that 'pressure in a void' is unnecessary to explain time-dependent brittle failure. In addition, they suggest the the possibility of unifying this behaviour with other, more familiar, phenomena which also are paced by the diffusion of interstitials, such as slow-strain-rate embrittlement and strain ageing[10].

Determination of Oxygen in Iron and Steel

WE have recently applied the method of stable isotope dilution[1] to the determination of oxygen in samples of iron and steel which contained low concentrations of this element. As our results are consistently higher than values obtained by the conventional vacuum-fusion method, this preliminary account of our work is submitted.

The technique consists of allowing the steel sample to react with carbon at 1,500° C. in an atmosphere containing a known amount of carbon monoxide enriched in the isotope oxygen-18. Measurement of the ratio $R = {}^{18}O/{}^{16}O$ in a sample of the gas after equilibration enables the oxygen content of the metal to be determined. 'Blank' corrections are negligible, but as an additional precaution may be avoided by prior equilibration of the graphite crucible used as container for the sample in an atmosphere containing the same relative amounts of oxygen-18 and oxygen-16 as the expected final equilibrium value R.

Various methods have been used to determine the ratio R. At first, use was made of the mass spectrometer ion currents at $m/e = 30$ and 28 due to singly ionized $C^{18}O$ and $C^{16}O$ respectively. Here, however, it is necessary to apply a correction, based on the ion current at $m/e = 14$, to the value at $m/e = 28$, because nitrogen from the steel is always present in the gas mixture at the end of a dilution. A more accurate method is to convert part of the carbon monoxide in the equilibrated gas mixture to carbon dioxide, and to measure the ion currents at $m/e = 44$, 46 and 48. The value of R is then given by either $2h_{48}/h_{46}$ or by $(h_{48}/h_{44})^{\frac{1}{2}}$, where h_x represents the ion current at $m/e = x$. The three methods yield results which agree within experimental error. Instrumental errors are avoided by using the same method for both calibration and analysis.

Calibration is effected by admitting to the furnace small measured quantities of normal and enriched oxygen in proportions similar to those encountered in an analysis. Conversion of carbon monoxide to dioxide without isotopic dilution is achieved by compressing part of the gas mixture from the furnace into a small circulatory system which contains a platinum filament heated to 900° C. and a trap cooled in liquid air. By this means the equilibrium :

$$2CO \rightleftharpoons CO_2 + C$$

is constantly displaced until sufficient carbon dioxide has been formed for analysis.

Table 1 summarizes the calibration and analytical results for a standard steel sample, designated *BPL*-21, supplied by the British Iron and Steel Research Association. The mean oxygen content of this steel as determined by several independent investigators with the vacuum-fusion method is given as 0·003 per cent, with an overall range of 0·002–0·004 per cent for individual determinations. Our values are thus higher by a factor of about two. The scatter between individual analyses is not improved.

It is estimated that the combined sources of error in the above analyses should not exceed ± 25 per cent for any single determination. In the analysis of several iron–carbon alloys prepared in this laboratory, results have been duplicated to within 10 per cent in the range 0·006–0·011 per cent oxygen. These figures were again higher than the corresponding vacuum-fusion results by a factor of two to four. The good reproducibility obtained with specimens

Table 1. Isotope Dilution Analysis of Sample *BPL*-21

					Mean	0 0070

prepared in the laboratory suggests that a large part of the scatter experienced with the British Iron and Steel Research Association standard may be due to inhomogeneities in the sample.

Steels containing manganese may be analysed by this technique if care is taken to introduce the enriched oxygen before the steel sample is dropped into the furnace. This precaution is necessary due to the rapidity with which the ferro-manganese film, which forms on the cold wall of the furnace, reacts with molecular oxygen. Analysis of a British Iron and Steel Research Association standard, designated *BNL*-21, which contained 0·44 per cent manganese, yielded a preliminary value of 0·0196 per cent for the oxygen content. This may be compared with the mean value of 0·0145 per cent reported for this steel by investigators using the vacuum-fusion technique.

Other work in progress in this Laboratory suggests that low results may be obtained for both oxygen and nitrogen by the vacuum-fusion method when the concentration of either of these elements is of the order of 0·01 per cent or less. If this is true, some revision of present accepted thermodynamic data may be necessary for alloys in this range of composition.

A full account of this work will be published elsewhere.

MINERALOGY

Determination of Tetrahedral Aluminium in Mica by Infra-Red Absorption Analysis

Continuation of studies[1] relating the infra-red absorption spectra and the aluminium substitution for silicon in the chlorite minerals has shown that a similar correlation exists in almost all micas. Regardless of the species under study (that is, muscovite, lepidolite, biotite, phlogopite), the shape of the 9–10μ region of the absorption spectra depicts the amount of aluminium substitution for silicon (*Y* number) in the basal, tetrahedrally co-ordinated level in the mica structure. The micas may be natural or synthetic. Position of the maxima of absorption is again dependent upon the dominant type of ion in the octahedrally co-ordinated level, the maxima shifting to slightly longer wave-length with increasing atomic weight of the ions in this position.

The aluminium content and distribution in a mica, therefore, can now be estimated by a rapid physical method. This is in marked contrast to experiences of previous workers[2] who have had great difficulty with differential solubility methods in estimating the aluminium in micas and clays.

In the dioctahedral micas, the aluminium in the octahedral level does not influence the shape of the infra-red absorption pattern, although, because of its lighter mass effect, the position of the maxima is shifted to shorter wave-lengths than with iron- and magnesium-bearing trioctahedral analogues. At first thought, it is strange that such a correlation should exist between *Y* number and absorption spectra, regardless of the mica species present. The tetrahedrally co-ordinated basal level in the mica structure, however, is common to all species; the ions differentiating the species from one another appearing in the octahedral and interlayer positions.

By the courtesy of people too numerous to mention in this short note, who have kindly sent us samples, we have been enabled to include the infra-red absorption curves of 22 analysed micas (Figs. 1 and 2). Members of the same mica species are listed in the vertical columns of curves, in order of decreasing *Y* number, so that horizontal comparison between micas with the same degree of aluminium substitution may be readily made. One of the muscovites and three of the biotites are not yet analysed, but

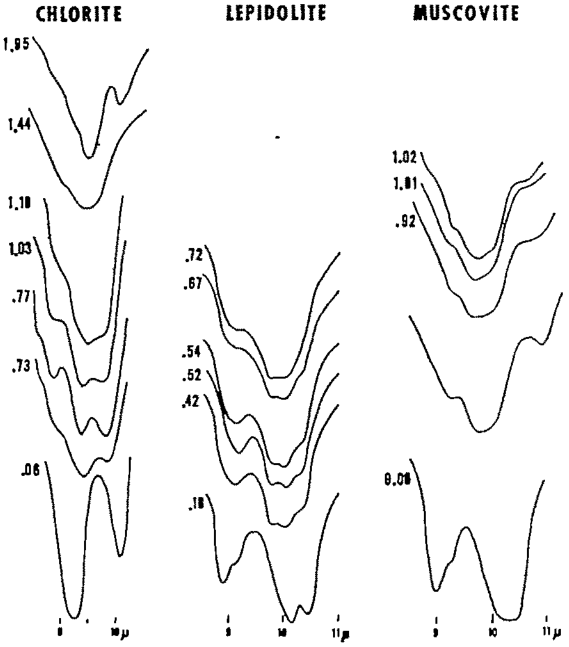

Fig. 1. Centre section (8 5–11μ) of infra-red absorption curves arranged in order of decreasing aluminium substitution for silicon (*Y* number). Curves in each species column are displaced vertically. Micas with equivalent *Y* number may be compared horizontally. Missing number for the muscovite curve is awaiting completion of chemical analysis

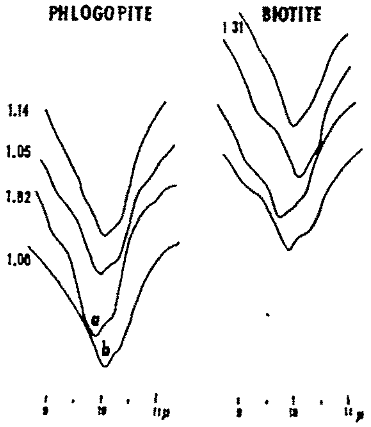

Fig 2. Centre section (8 5–11μ) of infra-red absorption curves for the phlogopite and biotite series. Arrangement as for Fig. 1. Phlogopite curves (*a*) and (*b*) have same Y number but are displaced laterally 0 2μ. Curve (*a*) is a magnesian phlogopite whereas (*b*) has a 1/8 iron substitution. Three of the biotites are not analysed at the present time

have been placed in relative position as deduced from the shape of their curves.

As with the chlorite series, the pure tetrasilicic end member ($Y=0$) (of at least the muscovite and lepidolite series) has a complex absorption pattern in the 9–10μ region. In addition to the normal broad absorption (or doublet) at 10·1–10·4μ, a pronounced doublet appears between 8·85 and 9 04μ. With increasing aluminium substitution, as Y rises from 0·4 towards 0·6, this doublet between 9·8 and 10·3μ becomes a triplet, with the short wave-length peak of this triplet becoming dominant as Y values increase above 0·9. The doublet at 9μ gradually fades out as Y increases towards unity, leaving the simplified, single absorption at 9·7–9·8μ.

Only one mica sample with Y value greater than 1·2 could be obtained. It may be that this value of 1·2 is again as critical in the broad groups of micas as it was in the chlorites[1], marking some type of structural change.

Difficulty has been experienced in relating the minerals talc and pyrophyllite to this scheme. Both possess effectively a zero aluminium substitution ($Y=0$), but their absorption spectra, which are very similar in pattern, consist of simple, single absorptions, suggesting a $Y=2$ situation as in the chlorite series. In addition, margarite, with a $Y=2$, has an unusually complex pattern and is markedly displaced to higher wave-lengths, compared with the septeamesite ($Y=2$) of the chlorite study.

It would be expected that the montmorillonite groups would show a similar correlation between Y number and infra-red absorption, although their lower degree of crystallinity would make the individual absorptions less distinct. Investigation of all these points is actively progressing.

CHEMISTRY

The α- and β-Forms of Calcium Sulphate Hemihydrate

Kelley, Southard and Anderson[1] have shown that the thermodynamic properties of calcium sulphate hemihydrate depend on whether the hemihydrate is produced from gypsum calcined in a steam-saturated atmosphere (α-hemihydrate), or under conditions where the partial pressure of water vapour is low (β-hemihydrate), but the nature of a hemihydrate prepared under conditions intermediate between these two extremes (for example, the manufacture of gypsum plaster by the kettle process) is not known for certain. These authors considered that such a hemihydrate would consist of a mixture of the α- and β-forms, but Eipeltauer[2] considered that there would also be some hemihydrate crystals having properties intermediate between these two forms. Work that I have done shows that only the α- and β-hemihydrates can be detected by differential thermal analysis in a sample of hemihydrate prepared by calcining gypsum under conditions simulating the manufacture of gypsum plaster in a kettle.

By means of differential thermal analysis it is possible to detect in a sample of calcium sulphate hemihydrate the various forms the rates of transformation from soluble to insoluble anhydrite of which vary[3], since each phase-change is shown by an exothermic peak at a particular temperature on the differential thermal curve. A sample of hemihydrate was prepared by heating 800 gm. of a washed natural gypsum for 5 hr. in a glass container filled to a depth of 3 in. (oven temp. 170° C.). The sample was cooled and then dried at 50° C., and the water content determined as 6·05 per cent (theoretical 6·21 per cent). The differential thermal curve for a partly dehydrated sample of this hemihydrate is shown in Fig. 1, curve *a*. The water content of the sample was reduced to about 1 per cent by heating for 1 hr. at 120° C., otherwise the exotherm shown at about 245° C. was completely absorbed in the large endotherm due to the loss of water from hemihydrate. After heating at 120° C. duplicate samples were allowed to rehydrate at 65 per cent relative humidity; resultant changes in weight indicated that the amount of insoluble anhydrite formed at 120° C. was very small. The exotherm shown at 245° C. on curve *a*

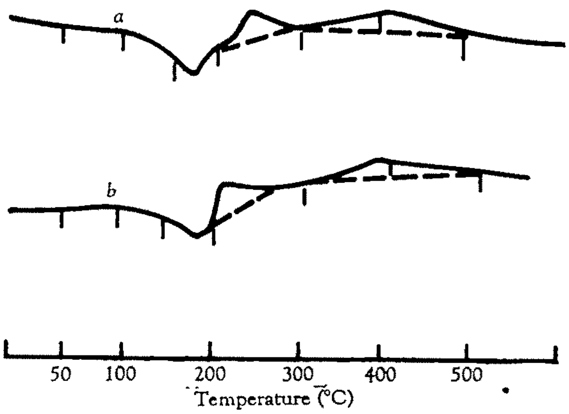

Fig 1. Differential thermal analysis curves for calcium sulphate hemihydrate (water content 1 per cent). *a*, a hemihydrate prepared under conditions simulating manufacture of gypsum plaster by the kettle process. *b*, a mixture of 70 per cent α-hemihydrate and 30 per cent β-hemihydrate

appears to be complete before the second exothermic reaction commences at about 300° C., and there is no indication of the decomposition of a phase intermediate between these two. The size and shape of the two exothermic peaks on curve *a* are very similar to those shown on curve *b*, which was obtained from a mixture of 70 per cent of α-hemihydrate, prepared by autoclaving, and 30 per cent β-hemihydrate. For comparison, the water content of this sample was also reduced to about 1 per cent prior to differential thermal analysis. The peak temperatures of the two exotherms on curve *a* occur at slightly higher temperatures than those on curve *b*, and the exotherm at 210° C. on the latter curve appears to commence before the small endotherm due to the loss of about 1 per cent water is complete.

The differential thermal analysis of a hemihydrate prepared as described above shows the presence of two main phases only, and by this technique it was not possible to detect a phase intermediate between the two. However, since the peak temperatures of the two exotherms on curve *a* occur at slightly higher temperatures than those for the mechanical mixture (curve *b*), this may indicate slight differences between different preparations of both α- and β-hemihydrates.

In general it was found that the proportion of each phase shown on the differential thermal curve could be determined more accurately from the area beneath the β-exotherm, because any insoluble anhydrite that might form during the preparation of a sample would be produced mainly from the more reactive α-phase. Since it has been shown that the α-exotherm is due only to the first rapid part of the transformation of α-soluble anhydrite to insoluble anhydrite[3] (the latter part of the reaction is slow and is not recorded by differential thermal analysis) the formation of small amounts of insoluble anhydrite prior to differential thermal analysis can greatly reduce the size of the α-exotherm.

Molybdenum and Niobium Sulphides

In the system Mo-S the only compound that is formed by direct synthesis from the elements is the disulphide MoS_2. This compound exists in two modifications:

(1) The well-known hexagonal form ($a=3·16$; $c=12·29$ A.), the structure of which[1] is shown in Fig. 1*a*.

(2) The rhombohedral form ($a=3·17$; $c=18·38$ A.) which was first described by Bell and Herfert[2]. These authors propose a $CdCl_2$-type structure which, however, is incompatible with their own and our X-ray diffraction data. Good agreement is found for the structure shown in Fig. 1*b*. This structure can be described in space-group $R3m—C^5_{3v}$: 3 Mo situated in 3(*a*) : 0 0 *z*, etc., with $z=0$; 3 S I in 3(*a*) with $z\approx\frac{1}{4}$ and 3 S II in 3(*a*) with $z\approx 5/12$.

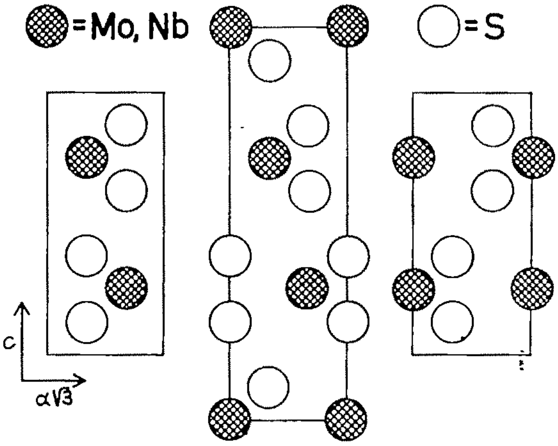

Fig. 1. Sections [through the (11$\bar{2}$0) planes of (*a*) hexagonal MoS_2, (*b*) rhombohedral MoS_2 and NbS_2, (*c*) hexagonal NbS_2

In both forms of MoS_2 the metal environment is trigonal prismatic. In synthetic molybdenum disulphides generally a considerable degree of stacking disorder in the *c* direction is present which causes a weakening of the reflexions with $h-k\neq 3n$, increasing with increasing value of *l*.

In the system Nb-S the following phases are observed:

(1) Monoclinic NbS_3 ($a=4·94$; $b=6·74$; $c=18·1$ A.; $\beta=97·5°$), which is probably isotypic with TiS_3 [3] and $ZrSe_3$ [4].

(2) Rhombohedral NbS_2 ($a=3·33$; $c=17·81$ A.), stable below about 800° C. This phase is probably identical with the disulphide found by Hägg and Schönberg[5], for which they propose a $CdCl_2$-type structure. This structure type, however, is in conflict with our intensity data; the structure we derive is isotypic with rhombohedral MoS_2 (Fig. 1*b*). Generally, stacking disorder in the *c* direction is observed; it can be diminished by annealing at 700–800° C.

(3) Hexagonal NbS_2 ($a=3·31$; $c=11·89$A.) is formed from the elements above 850° C. and is stable up to 1,050° C. The space group is $P6_3/mmc—D^4_{6h}$, the same as in the case of hexagonal MoS_2, but the structure is different. 4 S lie in 4(*f*) : $\pm(\frac{1}{3}, \frac{2}{3}, z; \frac{1}{3}, \frac{2}{3}, \frac{1}{2}-z)$ with $z\approx\frac{1}{8}$; 2 Nb either in trigonal prismatic holes 2(*b*) : $\pm(0\ 0\ \frac{1}{4})$ or in octahedral holes 2(*a*) : $0\ 0\ 0$; $0\ 0\ \frac{1}{2}$. X-ray diffraction can scarcely distinguish between these two arrangements, which are exactly homometric if $z_S=\frac{1}{8}$. Because of the analogy with rhombohedral NbS_2 and because of stacking arguments, position 2(*b*) is preferred (Fig. 1*c*). Once more, stacking disorder in the *c* direction is found.

(4) Rhombohedral $Nb_{1+x}S_2$ ($a=3·33$; $c=17·80$–$17·85$ A.), the range of homogeneity of which stretches from $x\approx 0·12$ to $x\approx 0·25$ at 1,100° C. and to $x\approx 0·5$ at 800° C. The structure which is shown in Fig. 2*a* can be described in space group $R3m—C^5_{3v}$: 3 Nb I in 3(*a*) : 0 0 *z*, etc., with $z=0$; $3x$ Nb II in 3(*a*) with $z\approx 5/6$; 3 S I in 3(*a*) with $z\approx\frac{1}{4}$; 3 S II in 3(*a*) with $z\approx 5/12$. The co-ordination of Nb I is trigonal prismatic, that of Nb II octahedral. Here, stacking disorder is inhibited by the presence of Nb II between the layers.

(5) Hexagonal $Nb_{1+x}S_2$ ($a=3·31$; $c=12·53$–$12·65$ A.) is stable above about 1,000° C. in the range $x\approx 0·30$ to $x\approx 0·43$. The space group is $P6_3/mmc—D^4_{6h}$; 2 Nb I are situated in 2(*b*) : $\pm(0\ 0\ \frac{1}{4})$; $2x$

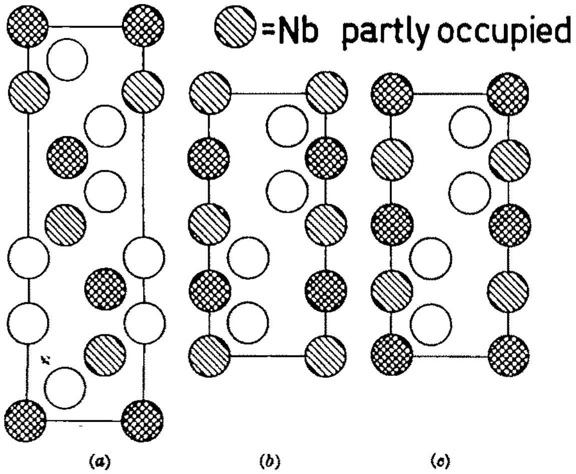

Fig. 2. Sections through the (11$\bar{2}$0) planes of (a) rhombohedral $Nb_{1+x}S_2$, (b) hexagonal $Nb_{1+x}S_2$, (c) one of the possible arrangements of $Nb_{2-y}S_2$

Nb II in 2(a) : 0 0 0 ; 0 0 $\frac{1}{2}$ and 4 S in 4(f) : $\pm(\frac{1}{3}, \frac{2}{3}, z;\ \frac{1}{3}, \frac{2}{3}, \frac{1}{2}-z)$ with $z \approx \frac{1}{8}$. This structure (Fig. 2b) seems more likely than the homometric arrangement with interchanged Nb I and Nb II positions, the reasoning being the same as in the case of hexagonal NbS_2. Again, stacking disorder is prevented by the presence of Nb II.

(6) Hexagonal $Nb_{2-y}S_2$ is stable below about 850° C. in the range $y \approx 0{\cdot}0$ to $y \approx 0{\cdot}3$. The X-ray patterns closely resemble those of hexagonal $Nb_{1+x}S_2$ and, therefore, the structure is either analogous to that of hexagonal $Nb_{1+x}S_2$ (Fig. 2b) with statistical vacancies in the 2(a) site, or to its homometric form with the vacancies in the 2(b) position (Fig. 2c). The possibility that hexagonal $Nb_{1+x}S_2$ and $Nb_{2-y}S_2$ belong to the same homogeneity range cannot be excluded. $Nb_{2-y}S_2$ is probably identical with the phase NbS described by Hagg and Schonberg[5]. These authors propose an NiAs-type structure for NbS with an excess of sulphur ($a=3{\cdot}32$; $c=6{\cdot}46$ A.) and a WC-type structure for NbS in equilibrium with Nb ($a=3{\cdot}32$; $c=3{\cdot}23$ A.). Evidently, Hägg and Schönberg overlooked the reflexions with $l \neq 2n$ which have rather weak intensities ; for $y=0$ the intensities of the reflexions with $l=4n+2$ become zero. Therefore, the c axes found by Hägg and Schönberg[5] are one-half and one-quarter of the actual one respectively.

(7) Above 850° C. one or more phases occur at compositions about NbS. The relationships in this range are rather complicated and not yet fully understood.

Details of these investigations will be reported elsewhere.

Oscillographic Investigation of Electrodeposition of Chromium

A great deal of work on the theory of electrodeposition of chromium has been carried out since 1920. E. Müller[1] reported the formation of chromium chromate film on the cathode surface and inferred the mechanism of chromium electrodeposition from the polarization phenomena. Recently D. Reinkowski and C. A. Knorr[2] fully examined the reproducibility of the cathode-polarization curves, and presented a new view of the existence of their different potential range and on the transition between these ranges. More recently, H. Gerischer and N. Käppel[3] postulated another theory of the chromic oxide film formed on the cathode surface, measuring the quasi-stationary potential-current curves using a potentiostatic method.

In the present communication, the charging curves during cathodic polarization at various current densities in the solution containing mainly 3 *M* CrO_3 were measured by the oscillographic method devised by A. Hickling[4]. The electrolytes used in this experiment were as follows: (a) 3*M* CrO_3, (b) 3 *M* CrO_3, 0·03 *M* sulphuric acid. The electrolytic temperature was always kept at 20° C. The charging curves at the platinum and gold electrodes during cathodic polarization at various current densities in the solution (b) are shown in Figs. 1*A* and 2*A*, respectively. The schematic representations of these curves at 20 amp./sq. dm. are shown in Figs. 1*B* and 2*B* respectively. The ordinates represent the potentials vs. *S.C.E.* and the abscissæ are proportional to the quantities of electricity passed. In solution (a), at all current densities the charging curves were the same tracks as those obtained in the solution (b) at 20 amp./sq. dm.

The tracks of the charging curves at 20 amp./sq. dm. in solution (b) passed through four inflexion points (1, 2, 3 and 4 from positive potentials to negative), and reached the constant potentials, forming the three stages (a, b and c), as shown in Figs. 1*B* and 2*B*.

In comparison with the current-potential curves in solution (b) at both electrodes (see Figs. 5 and 7 of ref. 2), which consisted of four or three different potential-ranges, it may be noted that the inflexion points (2) (+192 mV. at the platinum electrode, +674 mV. at the gold electrode) approximately correspond to the ends of the first stages of the polarization curves, in the same manner (3) (−268 mV. (platinum) +296 mV. (gold)) to the ends of the second stages, (4) (−412 mV. (platinum), −780 mV. (gold)) to the beginning of the third or fourth stages. At the lower current densities (5 amp./sq. dm.,

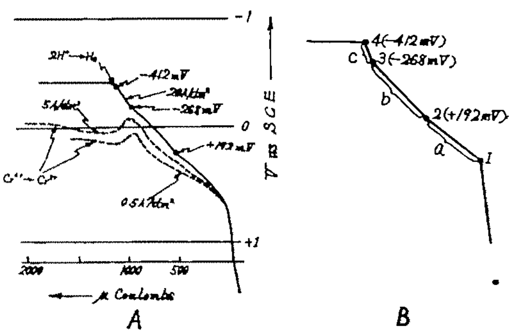

Fig. 1. *A*, Charging curves of the platinum electrode during cathodic polarization in the solution (b) at various current densities ; *B*, schematic representation of Fig. 1 at 20 amp./sq. dm.

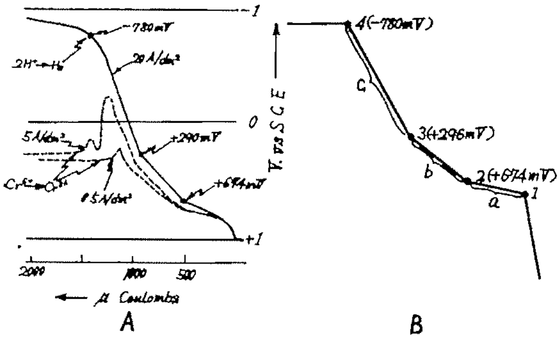

Fig. 2, *A*, The charging curves of the gold electrode during cathodic polarization in the solution (*b*) at various current densities, *B*, the schematic representation of Fig. 2 at 20 amp./sq. dm.

0·5 amp./sq. dm.) in solution (*b*) the tracks of the oscillograms did not reach the inflexion points (4), but gave constant potentials at the inflexion points (3) or (2). At these potentials only the reduction process of Cr^{6+} to Cr^{3+} occurred.

A. Hickling[4,5] and S. E. S. El Wakkad *et al.*[6,7] studied the reduction of the oxide films of platinum and gold electrodes, measuring the charging curves of these electrodes during cathodic polarization. In comparison with their results (see Fig. 9 of ref. 6 and Plate II, I of ref. 5), it is seen that the stages (*a*) in Figs. 1 and 2 correspond to those of the reduction processes of PtO and Au_2O_3, respectively. F. Baumann and I. Shain[8] found that the reduction process of Cr^{6+} to Cr^{3+} occurred soon after the reduction of the oxide film of the gold electrode, using a gold rotating electrode. Consequently, it is considered that at stage (*a*) the reduction of the oxide films of these electrodes occurs.

From the fact that the stage (*b*) exhibited the same slope at both electrodes, that is, platinum and gold, it is suggested that the same electrode reaction occurs. The inflexion points (3) corresponded to the ends of the second stages on the polarization curves, and at the ends of these stages the electrodes should be fully covered with chromium chromate film. Therefore, it is considered that stage (*b*) exhibits the quantity of electricity required for the formation of this film. The number of ions of Cr^{3+} formed on the stage (*b*) were evaluated from the quantity of the electricity: at the platinum and gold electrodes these are $1{\cdot}00 \times 10^{15}$ ions/sq. cm. and $1{\cdot}37 \times 10^{15}$ ions/sq. cm., respectively. The number of atoms of platinum and gold per sq. cm. at the platinum and gold surfaces are, respectively, $1{\cdot}61 \times 10^{15}$ atoms/sq. cm. and $1{\cdot}50 \times 10^{15}$ atoms/sq. cm. Considering the uncertainty of the exact values of the surface areas of both electrodes, it may be considered that the quantities of electricity necessary for the formation of the films approximately correspond to the formation of a unimolecular film of chromium (III) on the electrodes, and this quantity of electricity at the platinum electrode is in fair agreement with the value obtained by I. M. Kolthoff and A. M. S. El Din[9].

The significance of the four stages of the polarization curve in the solution (*b*) (chromium plating solution) has not been fully explained; and D. Reinkowski and C. A. Knorr[2] have indicated that the second stage exists in the different potential range depending on the electrode material.

From the above results, it is considered that at the first stage of the polarization curve the reduction of the oxide film of the electrode occurs in the case of platinum and gold electrodes, and that the film of chromium chromate forms soon after this reduction process occurs. Consequently, the fact that the first and the second stages of the polarization curve exist at the different potential ranges, depending on the electrode materials, was attributed to the differences in the reduction potentials of the oxide films of the electrodes.

A Synergic Method of carrying out Continuous Electrochromatography

ALTHOUGH some workers using the technique of continuous electrochromatography on conventional anticonvection media (such as filter paper or glass powder) have supposed that specific adsorption effects play a part in the separation, the extent to which these can in fact influence the separation, if at all, is negligible. The adsorbed Stern layer ions are practically immobile with respect to both electrophoretic and hydrodynamic gradients; thus even notionally, since each is equally affected, the resultant of motion in the two mutually perpendicular directions should be independent of the degree of adsorption. Weber[1] has considered the general differential equation describing the concentration distribution (as a function of space and time) in terms of diffusion, adsorption, and the two velocities, on the assumption that adsorption equilibrium is reached instantaneously. The solution of this equation for the stationary state does not involve an adsorption term.

It seems likely that improved electrochromatographic separations might be achieved by substituting ion-exchange membrane 'curtains' for paper ones. In this way a stationary phase capable of highly selective sorption could be provided, within which particles would be immobilized with respect to eluant flow but not with respect to current flow. Consequently the change brought about in mobility ratios might be expected to differ from that brought about in retention-volume ratios; and in certain systems at least the direction of these changes might be such as to give rise to synergy between electrophoresis and chromatography. An analysis of the situation shows that this expectation is well founded. If we define a 'separation coefficient' $D^1{}_2$ as the ratio $\tan\theta_1/\tan\theta_2$, where θ is the angle through which the path of a given species is swept from the vertical under the influence of an applied potential, then the following relations can be derived:

Ion-exchange resin absent:

$$D^1{}_2 = \frac{u_1}{u_2} \cdot \frac{\rho^0{}_2}{\rho^0{}_1} \qquad (1)$$

Ion-exchange resin present (volume of eluant per gm. resin small):

$$D^1{}_2 = \underbrace{\frac{\bar{u}_1}{\bar{u}_2}}_{\text{electrophoretic factor}} \cdot \underbrace{\frac{\rho^r{}_2}{\rho^r{}_1} \cdot \frac{K^0{}_1}{K^0{}_2}}_{\text{chromatographic factor}} \qquad (2)$$

The first term in each case is a ratio of mobilities, measured in the free eluant in (1) and in the resin in (2). The third term in (2) is the ratio of specific retention volumes, measured in the *absence* of any complexing agent in the eluant. The second term arises from the possible presence of a ligand. The quantity ρ_i is the ratio (total concentration of species i in eluant)/(concentration of uncomplexed species i in eluant), and depends on the concentrations of both i and ligand as well as pH. The superscripts denote presence or absence of ion-exchange resin, since this factor is altered by the equilibria displacements resulting from the introduction of resin. In the derivation it is assumed that the mobility of the complexed species is negligibly small in comparison with that of the uncomplexed species, that diffusion can be neglected and exchange equilibria regarded as instantaneous, and that the resin is lightly loaded.

Comparison of equations (1) and (2) shows at a glance why synergy arises when an ion-exchanger is introduced into the system. In general one can say, for a series of like ions, that the greater the mobility of an ion the greater its affinity for an ion-exchange resin and the lower the stability of its complexes[2]. Furthermore it can be shown that the 'complexone affinity' term in equation (2) is very much further from unity than that in equation (1) for a given total concentration of complexone, unless vanishingly small quantities of material are to be separated. (In the absence of complexone it is, of course, unity.) This is an important effect *per se*.

A suitable arrangement for separations of this kind consists of a pack of ion-exchange membranes interleaved with filter paper or similar material to act as flow stabilizer. This has the advantage over a trough filled with fine resin granules in that it is relatively easy to obtain uniform flow. Moreover, membranes of high selectivity are likely to become more readily available than their granular counterparts. For a given system the coefficient $D^1{}_2$ can be evaluated most simply by carrying out separate electrophoretic and chromatographic separations on strips of paper or paper–membrane–paper sandwich. Such strips are readily examined spectrophotometrically or radiometrically, and it is only necessary to divide the ratio x_1/x_2 of distances moved in an electrophoretic run by the corresponding ratio for a chromatographic run carried out under the same conditions. Runs have been performed on single strips of sulphonated polyvinyl chloride membrane[3] 3 cm. wide and 30–45 cm. long sandwiched between two strips of 'Separa *DHC*' paper (W. and R. Balston, Ltd.) of the same width. For convenience the system sodium-22 (2·6 yr.)–potassium-42 (12·4 hr.) was chosen for study. The membranes were used in the dimethylammonium form; the eluant (electrolyte) contained uramil-N,N-diacetic acid and dimethylamine, its pH being determined by the concentration of the latter. Similar conditions have been employed successfully to resolve mixtures of alkali ions on ordinary ion-exchange columns[4]. The electrophoretic runs required about 0·04 ampere-hours at 750 volts.

The results obtained in a series of experiments with the membrane are compared with those for paper alone in Fig. 1. The strips were loaded with 0·5 μmole of each ion. It is seen that although the mobility ratio is somewhat decreased in the presence of membrane its pH dependence parallels the behaviour in the absence of membrane. On the other hand the corresponding chromatographic ratio, in the presence of membrane, undergoes a sharp decrease between pH 8 and 9. This can be traced to the operation of the complexone affinity term in equation (2). Although in this system the membrane itself exhibits no noticeable préference, the synergic influence of the chromatographic component in its presence is evident.

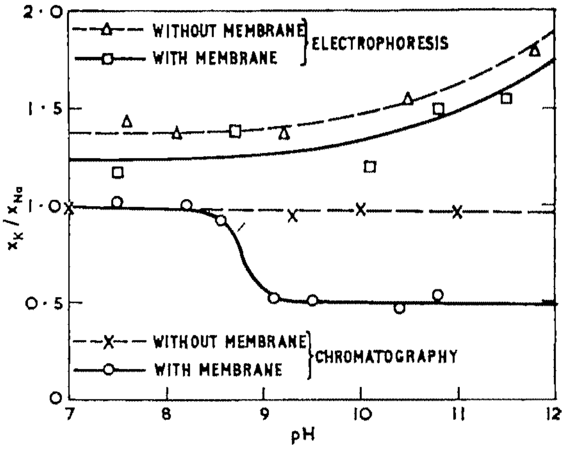

Fig. 1. Evaluation of a system by means of strip experiments

A full account of this work, including a comparison of several membranes and a description of a working cell used for the separation of lithium, sodium and potassium, is in preparation.

Reduction of Graphite by Lithium-Ethylenediamine

It is well known that coals can be converted to liquid fuels by catalytic hydrogenation at high temperatures and pressures. However, coals of high rank (>89 per cent carbon m.a.f.) are liquefied in poor yield[1]; anthracites (>92 per cent carbon m.a.f.) are very difficult to hydrogenate; and graphite cannot be hydrogenated to liquid or solid products.

Recent work in this laboratory[2] has shown that coals and vitrains containing up to 92 per cent carbon can be reduced by the lithium-ethylenediamine system[3]; hydrogen is added, no carbon–carbon bonds are broken, and the reaction takes place under the mild conditions of 115° and atmospheric pressure.

Table 1

	C	H	N	Ash	O (diff.)	gm. H_2 added per 100 gm.	gm. H_2O added per 100 gm.
Graphite, starting material*	98·90	0·29	0·07	0·87	−0·13		
Graphite, reduced*	85·39	2·91	3·83	6·28	1·59		
Graphite, starting material†	99·79	0·29	0·07	—	−0·15		
Graphite, reduced†	95·95	2·12	0·07	—	1·86	1·65	2·85

* Actual analytical values.

† Analytical values corrected to a moisture-, ash- and ethylenediamine-free basis

The insolubility of graphite in ethylenediamine should hinder its reduction; on the other hand, it is already known that even an insoluble anthracite is reduced by lithium-ethylenediamine; further, the graphite structure consists almost entirely of carbon–carbon single and double bonds, and the latter are readily reduced by lithium-ethylenediamine.

Three gm. of Madagascar flaky graphite (previously de-ashed by treatment with hydrofluoric acid) was reduced with 6·80 gm. of lithium and 150 ml. of ethylenediamine[2]. The recovered material weighed 3·11 gm. Table 1 gives the analytical values for the product. The graphite after reduction retains nitrogen, probably in the form of chemically combined ethylenediamine; this is the same behaviour found with coal. A correction must be made for this combined ethylenediamine, since it contains hydrogen. Table 1 gives the analytical composition of the graphite, corrected to a moisture-, ash-, and ethylenediamine-free basis. The value of 1·65 gm. of hydrogen added per 100 gm. of starting graphite seems remarkably high, particularly when the mildness of the conditions used is considered. This value of 1·65 gm. corresponds to addition of 19·7 atoms of hydrogen per 100 carbon atoms in the original graphite. This is much lower than the value of 44·8 atoms of hydrogen per 100 carbon atoms found for a high-rank bituminous vitrain[3] (90·4 per cent carbon m.a.f.), but it compares favourably with the value of 16·9 found for an anthracite[3].

To determine the effect of the treatment on the graphite lattice, X-ray diffraction patterns of the treated sample were examined. The patterns of the untreated and treated graphite (Fig. 1) were obtained from compressed slab specimens by the reflexion method. The (002) band of the treated sample was greatly decreased (not obvious on Fig. 1) and broadened and has a peculiar shape. Furthermore, a distinct band has been formed at a *d*-spacing of 4·82 A. Lithium is known to form interstitial compounds with graphite. The reduced sample was analysed and found to contain 1·5 per cent lithium. To decrease the lithium content, the sample was treated with hydrochloric acid and washed. It then contained 0·47 per cent lithium. The X-ray patterns of the sample before and after this treatment were identical; that is, the (002) and 4·82 A. bands were not affected. The large amount of nitrogen present is somewhat disturbing; however, it appears that hydrogen atoms have been added to the graphite lattice to produce hydrogenated layers. The average distance between parallel adjacent alicyclic units is estimated to be 4·7–4·9 A.

X-ray examination of the compressed slab specimen by the transmission method revealed that the (*hkl*) reflexions were also reduced and broadened. This suggests that treatment of graphite flakes with lithium-ethylenediamine effectively reduces the size of crystals, in particular the stacking height.

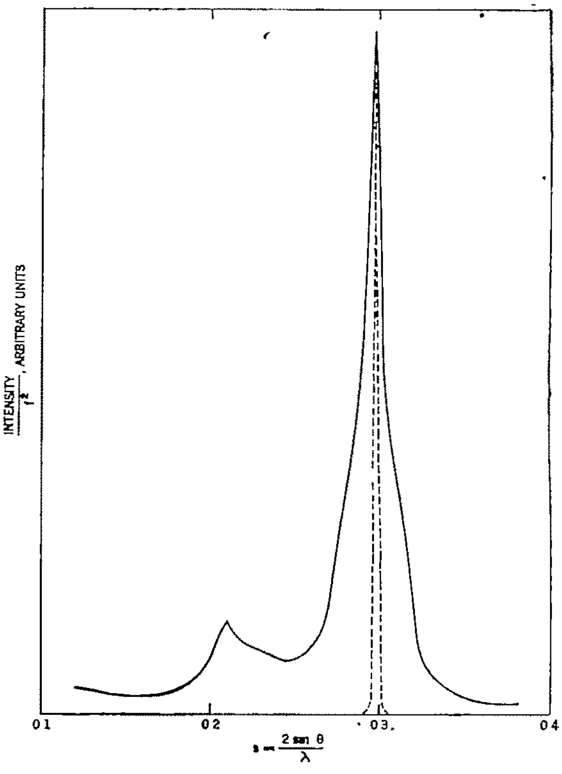

Fig. 1

We wish to thank V. Tiensuu for assistance in the interpretation of the X-ray patterns.

BIOCHEMISTRY

Violinoid Products of Oxidation of *d*-Urobilin

Some confusion has recently arisen over the nature of the pigments derived from *d*-urobilin (I) by treatment with methanolic ferric chloride in the presence of hydrochloric acid. Watson[1] claims that this urobilin, after treatment for 15 min. under conditions similar to those described below, affords mainly glaucobilin (II). This finding differs from our own[2], which suggested that mesobiliviolins were the main products. Watson obtained mesobiliviolin only after brief treatment of *d*-urobilin with ferric chloride.

We have now confirmed that our original conditions of oxidation[2] convert *d*-urobilin mainly to violinoid pigments (λmax. 560–600 mμ in 2·8 *N* hydrochloric acid, 570 mμ in chloroform and 630,580 mμ for the zinc complex in methanol; these bands being

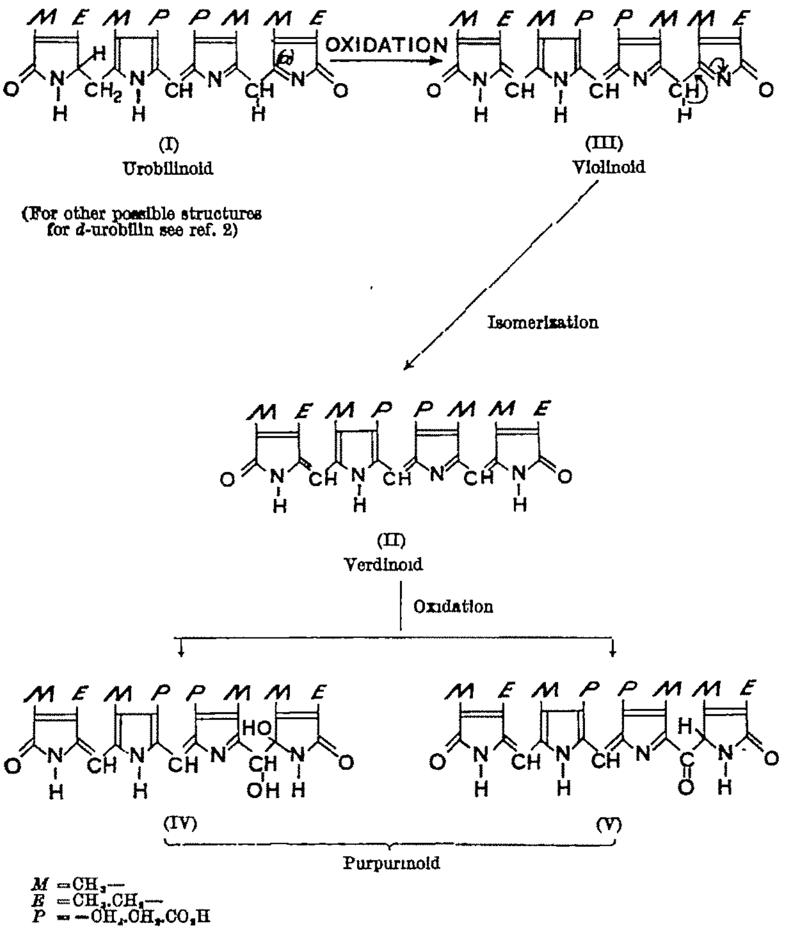

Fig. 1

diminished with formation of a third band at 510 mμ on addition of iodine). We have also found that further treatment with ferric chloride converts these violins to glaucobilin, so that they must be true violins, that is, bilidienes (III)[3]; and not the spectroscopically similar bilipurpurins[4], that is, compounds like (IV) and (V) derived from verdins (II) by oxidative saturation of one methene group. Further study of the problem has shown that even minor changes in our procedure can, according to conditions, give glaucobilin, mesobiliviolin, mesobilipurpurin or a mixture of these pigments. The nature of the products depends, among other things, upon the time of ferric chloride oxidation, dilution of the reaction mixture and extraction of products.

200-μgm. quantities of *d*-urobilin hydrochloride, with $(\alpha)_D$ (in chloroform) +5,000, were obtained by evaporation of appropriate volumes of chloroform solution. After solution in 2 ml. methanol the pigment was boiled, under reflux, with 1 ml. of 25 per cent (w/v) solution of ferric chloride in 11 *N* hydrochloric acid. After addition of 4 ml. of saturated aqueous sodium acetate solution and sometimes dilution, the oxidation products were extracted into ether. The pigments were taken from ether into 2·8 *N* hydrochloric acid; absorption spectra of the acid solutions were measured and the pigments were extracted into chloroform. After washing and filtration the spectra were again determined.

When the solutions were boiled for 10–15 min. and the pigments extracted without dilution, glaucobilin accompanied by small quantities of violin was formed, as was apparent from the absorption spectra. On refluxing for 15–18 min. the reaction mixture, still initially green, on dilution rapidly (1–5 min.) acquired a pink-violet colour due to the formation of violinoid pigments (λmax.: 540–560 mμ in chloroform, 580–590 mμ in 2·8 *N* hydrochloric acid and 620, 575–585 mμ for the zinc complex in methanol; on addition of iodine to the last solution there was depression of the existing two peaks, and an additional peak appeared at 510 mμ). These pigments would not undergo further oxidation to verdin on treatment with ferric chloride and were therefore assumed to be purpurins rather than true violins; the behaviour of their chloroform solution on treatment with 1 per cent hydrochloric acid suggests that they are in fact mesobilipurpurins-II (for example, V)[4]. Refluxing for 30 min. gave a reaction mixture from which glaucobilin alone could be isolated independently of dilution or interval between end of reaction and extraction of product.

It is evident that glaucobilin formation by oxidation with ferric chloride is more rapid than the corresponding reaction with *i*-urobilin. We suggest that a possible reason for this is that violin, initially formed by dehydrogenation of one bridge carbon atom and its adjacent α-pyrrole carbon atom, undergoes rapid isomerization to verdin by the prototropic change formulated in Fig. 1. A similar change is impossible for *i*-urobilin since it lacks the necessary unsaturation (*a*) present in *d*-urobilin[2].

In agreement with this mechanism is the fact that *d*-urobilin can be isomerized to a true violin, unaccompanied by glaucobilin, by anaerobic treatment with alkoxides; these are effective catalysts for changes such as those shown in Fig. 1[5,2]. The mechanism is, however, not in accord with a recent observation of Watson (private communication) that in ferric chloride oxidation *d*-urobilin IXα behaves more like *d*-urobilin than *i*-urobilin. If this observation is confirmed, the structures postulated for *d*-urobilin and *d*-urobilin-IXα[2] may need revision, for the latter has hitherto been considered optically isomeric with *i*-urobilin.

Activating and Fluorescent Wave-lengths of Furocoumarins : Psoralens

Biological photosensitized reactions are known to result from the absorption of a wide spectrum of radiation. The energy and therefore the wave-length of light absorbed and the biological changes occurring in photosensitized reactions are obviously closely related. A fundamental law of photochemistry, the Grotthus–Draper law, states that only radiation absorbed by the reacting system is effective in producing chemical change. Thus the radiation producing the photosensitizing reaction (that is, the action spectrum) should correspond to the absorption spectrum of the photosensitizing agent.

The furocoumarins, more generally known as psoralens, have been shown to be highly active photosensitizing agents capable of inducing sunburn or erythema and augmenting the skin pigmentation[1-3]. Furthermore, these compounds inhibit enzymatic activities as well as exhibit bactericidal and fungicidal effects following ultra-violet irradiation[4-7]. Their effect on ultra-violet carcinogenesis in albino and pigmented mice has also been investigated[8,9]. In most of these studies long-wave ultra-violet light has been observed by several investigators to be more effective in evoking these biological responses. The precise activating wave-length range was not known. In the course of examining the photosensitizing activity of 45 natural and synthetically prepared

psoralens, it has been observed[10,11] that linearly annulated condensed tricyclic structure of psoralen exhibited optimum photosensitization on human as well as guinea pig skin.

Since fluorescence behaviour represents the emission from the activated molecules of absorbed light energy, we investigated the activating and the fluorescent wave-lengths of 37 furocoumarins and their biological photosensitizing action (Table 1). An Aminco–Bowman spectrophotofluorimeter was used in this study[12]. Each compound was dissolved in 95 per cent ethanol (1 mgm./10 ml.) and an aliquot used for determining the activation and fluorescent wave-lengths. The method for determining the biological photosensitization of furocoumarins and their relative activity as measured by erythemal response has been detailed elsewhere[10,11].

As indicated in Tables 1 and 2, the region of activating wave-lengths for photosensitizing action of furocoumarins lies between 265 and 280 mμ in the short ultra-violet range and between 340 and 380 mμ in the long-wave ultra-violet range. The fluorescence peaks for these activating wave-lengths were observed in the region of 420–460 mμ. The percentage fluorescence emitted was always significantly high when the activating wave-lengths were 340–380 mμ. Furocoumarins which induced definite photosensitized erythemal response on mammalian skin (human as well as guinea pig) showed this region of exciting wave-lengths. The inactive furocoumarins which did not exhibit photosensitizing response in general did not show these specific activating and fluorescent peaks. It appears that furocoumarins which show activation peaks in the region of 340–380 mμ and concomitantly the fluorescent peaks in the region of 420–460 mμ can cause photosensitization of skin in this region of long-wave ultra-violet light. The action spectra for these photosensitizing compounds therefore appears to be in the region of 340–380 mμ.

The interest of Dr. Farrington Daniels, jun., and Dr. Thomas B. Fitzpatrick in this work is gratefully acknowledged. We also wish to thank Dr. K. D. Kaufman, Kalamazoo College, Kalamazoo, Michigan, the Paul B. Elder Company, Bryan, Ohio, the Upjohn Company, Kalamazoo, Michigan, and Dr. A. Chatterjee, University College of Science and Technology, Calcutta, India, for providing compounds for this study.

This investigation was supported by United States Public Health Service grant number *C*-2837 (*C*3) and *B*-1572 (*C*151).

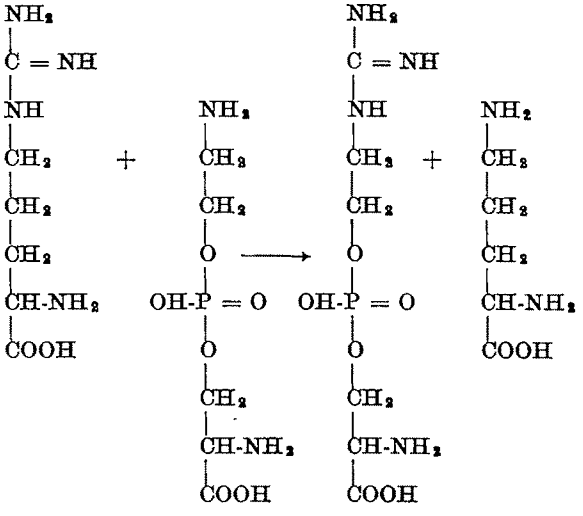
Biosynthesis of Lombricine

It was previously suggested[1,2] that serine ethanolamine phosphodiester (I) was the biological precursor of lombricine (II), a substance first isolated from earthworms by Thoai and Robin[3]. This suggestion was strengthened by the discovery of serine ethanolamine phosphodiester in earthworms[2,4] and by the finding that the serine moiety of both lombricine[5] and serine ethanolamine phosphodiester[4] had the unusual D-configuration. Experiments with inorganic phosphorus-32, [1 : 2-^{14}C] ethanolamine and DL-[3-^{14}C] serine have now provided additional evidence for this view. Furthermore, experiments with L-[amidino-^{14}C] arginine have shown that the amidino group of lombricine is derived from the amidino group of arginine (III), probably by a transamidinase catalysed transfer of the amidino group to serine ethanolamine phosphodiester with the formation of ornithine (IV):



(III) (I) (II) (IV)

The labelled precursors were administered to earthworms (*Megascolides cameroni*) in the amounts and specific radioactivities shown in Table 1. The labelled substances were given from a micro-syringe through a fine polythene tube inserted into the gastrointestinal tract of the worm for a distance of at least 3 cm. After the stated interval of time the worm was killed for the determination of the specific radioactivities of serine ethanolamine phosphodiester and lombricine (Table 1). The muscle was dissected out and extracted with 1·5 *N* perchloric acid. The extract was neutralized and then desalted on a 'Zeokarb 225' ion-exchange column (H$^+$ form). After concentration, the serine ethanolamine phosphodiester and lombricine were separated chromatographically on sheets of Whatman No. 3 filter paper with the solvents ethanol/formic acid/water (17 : 10 : 20 by vol.) and phenol/water (4 : 1 w/v). The specific radioactivities of the eluted serine ethanolamine phosphodiester and lombricine were determined using standard techniques. In some experiments the eluted lombricine was hydrolysed for 24 hr. at 110° in the presence of 6 *N* hydrochloric acid in a sealed tube, for determination of the distribution of radioactivity in the lombricine molecule (Table 2). The products of hydrolysis were separated chromatographically on paper strips with the phenol/water solvent. Serine from the serine moiety of lombricine and a combined area, representing guanidinoethanol

Table 1. *In vivo* INCORPORATION OF RADIOACTIVITY FROM LABELLED PRECURSORS INTO SERINE ETHANOLAMINE PHOSPHODIESTER AND LOMBRICINE OF EARTHWORM MUSCLE

Precursor	Amount administered (μmoles/gm.)	Radioactivity administered (c.p.m./gm.)	Time intervals (days)	Specific radioactivity (c.p.m./μmole)	
				Serine ethanolamine phosphodiester	Lombricine
Inorganic ^{32}P ..	carrier-free	$1{\cdot}1 \times 10^{6}$	2	560	20
Inorganic ^{32}P ..	carrier-free	$1{\cdot}1 \times 10^{6}$	4	840	97
[1 : 2-^{14}C] ethanolamine	3·7	$7{\cdot}5 \times 10^{6}$	4	67,900	1080
DL-[3-^{14}C] serine	2	10^{7}	2	31,500	904
L-[*amidino*-^{14}C] arginine	40	10^{6}	2	negligible*	329

* Net counting rate less than one-half the background counting rate.

Table 2 DISTRIBUTION OF RADIOACTIVITY IN LABELLED LOMBRICINE OF EARTHWORM MUSCLE

Precursor	Counts in serine moiety (per cent of total)	Counts in guanidinoethanol moiety (per cent of total)
[1 : 2-^{14}C] ethanolamine	6	94
DL-[3-^{14}C] serine	76	24
L-[*amidino*-^{14}C] arginine	negligible*	97

* Net counting rate less than one-half the background counting rate.

and guanidinoethyl phosphate from the guanidinoethanol moiety, were eluted for further counting.

After the administration of inorganic phosphorus-32, [^{14}C] ethanolamine and [^{14}C] serine, the specific radioactivity of the serine ethanolamine phosphodiester was much greater than that of the lombricine (Table 1), which is consistent with the view that serine ethanolamine phosphodiester is a precursor of lombricine and not a degradation product of that molecule. Table 2 shows that with [^{14}C] ethanolamine almost all the radioactivity was in the guanidinoethanol portion of the lombricine molecule, whereas with [^{14}C] serine most of the radioactivity was in the serine portion.

In contrast to the findings for inorganic ^{32}P, [^{14}C] ethanolamine and [^{14}C] serine, when L-[amidino-^{14}C] arginine was administered to the earthworm there was negligible radioactivity in the serine ethanolamine phosphodiester and considerable activity in the lombricine (Table 1). Almost all the radioactivity was in the guanidinoethanol moiety of the lombricine, indicating that at least one carbon atom of that portion of the molecule was derived from the carbon atom of the amidino group of arginine.

These findings strongly suggest that in the earthworm under *in vivo* conditions serine ethanolamine phosphodiester is the precursor of lombricine and that the amidino group of lombricine is derived from arginine by a transamidinase catalysed reaction.

Dependence of Periodic Activation and Inhibition of Monoaminoxidase by Aliphatic Compounds upon Chain-length

MONOAMINOXIDASE has been linked with vascular and mental activity[1-3]. Among the most ancient modifiers of mental status are the alcohols, which have been shown[4] to modify monoaminoxidase *in vitro*. During our endeavours to develop this correlation further, we encountered a puzzling periodic activation and inhibition of this enzyme. For five years, the postulation of a tenable explanation has escaped not only our own interpretative capacities, but also those of the recognized specialists whom we have consulted. The recent studies of aliphatic compounds which have accompanied the discovery of irin[5] have provided our experiments with added interest: it now seems possible that enzymatic modification by aliphatic compounds might constitute a regulatory mechanism in the contraction of smooth muscle.

The determinations of monoaminoxidase activity were performed on rat liver homogenates and on isolated mitochondria with analytical methods previously discussed[6]. Among them the most reliable one[7] is the simple measurement of ammonia evolution[8]. Therefore only the results obtained with that method are shown here, although respirometry yielded qualitatively similar results whenever concomitantly performed.

The modification of the aminoxidase activity in a liver homogenate as a function of the chain-length of normal aliphatic alcohols is shown in Fig. 1. The alcohols had been subjected to elemental analysis which showed the absence of significant contaminants. The molarity of the alcoholic additives was $1{\cdot}5 \times 10^{-6}M$ for all the samples; the controls had saline added. The substrates were the hydrochlorides of tyramine and 1-norepinephrine (50 μmoles per ml. of reaction mixture). Short pre-incubations of the samples with the alcohols alone did not materially affect the results. The incubations were carried out at 4°C. since the modification was less pronounced at 37°C. and was diminished even more by higher temperatures. The results are expressed as percentages of the average reaction velocity of the control. The tyramine experiment is represented on the left ordinate and the norepinephrine results on the right. It is evident that the maxima and minima differ between the two substrates.

We have shown earlier that monoaminoxidase is intimately attached to the mitochondria of the rat liver cells[9] and that it may be rendered water-soluble by the use of suitable detergents[10]. At present, the most convenient detergent seems to be 'Igepal CO-630'[11]. As reported previously[10], the solubilization of this enzyme is accompanied by a significant increase in measurable activity. Thus it was of interest to determine whether the periodic phenomenon here discussed depended on the existence of intact mitochondria or whether the water-soluble enzyme-detergent complex also was capable of activation-inhibition with alcohols. Results with solubilized enzyme are summarized in Fig. 2 in the fashion discussed above. The normal alcohol concentration was $1{\cdot}8 \times 10^{-5} M$. It is noteworthy that the activation phase was evident only with norepinephrine and that with this substrate the maxima and minima were shifted as a result of the enzyme's solubilization.

Long ago, Blaschko[12] published a summary of his experience with the oxidation of aliphatic diamines of various chain-lengths by monoaminoxidase preparations. We interpret this activity curve as being periodic. Furthermore, what we consider as being the maxima in Blaschko's curve correspond to the minima in our tyramine curve, while his minima correspond to our maxima. Thus the two are essentially enantiograms of each other. It seems, therefore, that the phenomenon which we have encountered with alcohol additives might also be occurring when a homologous series of substrates are tested without any additive. It is also pertinent that the enzyme under discussion is sensitive to the substrate concentration, since we have described earlier[6] a marked temperature-dependent inhibition caused by high substrate concentrations. It was of interest therefore to study permutations of homologous series of substrates and of alcohols in order to discover the nature of the complementarity displayed by this system. As yet we have been unable to secure a homologous series of substrates in sufficiently pure form for enzymatic work.

In an effort to discover other aliphatic modifiers, we have investigated several series of aliphatic compounds. Of these the normal hydrocarbons have shown a behaviour qualitatively similar to the alcohols: a progressively increasing inhibition of the aminoxidase reaction was seen when the gaseous hydrocarbons were added to the atmospheric oxygen in equimolar concentrations. With the liquid hydrocarbons the modification of the enzyme occurred only in some of the experiments. When it did occur, it was as pronounced as with the alcohols. We have not as yet discovered the variable which caused this all-or-none response of our preparations. The normal saturated fatty acids and their methyl esters were inactive in several experiments.

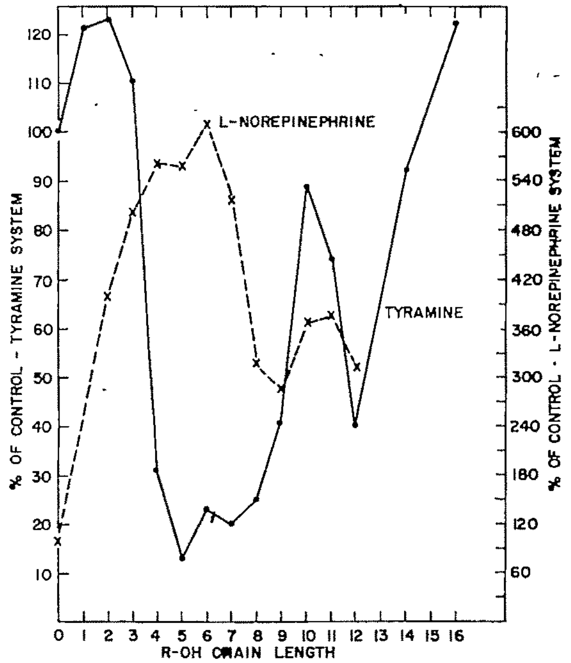

Fig. 1. Effect of chain-length of *n*-alcohols on monoaminoxidase activity of rat liver homogenate, as measured with the substrates indicated

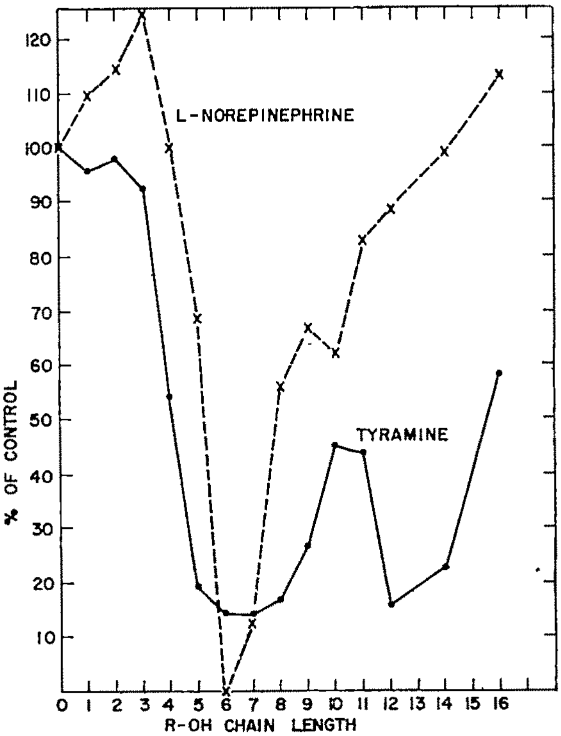

Fig. 2. Same as Fig. 1 but the homogenate was solubilized with detergent

It is evident that mammalian aminoxidase is amenable to periodic activation and inhibition by homologous series of some aliphatic compounds *in vitro*. The mechanism of this interesting phenomenon as well as its possible *in vivo* counterparts will require further work for their final definition.

Effect of Nitroacridine 3663 on Synthesis of Deoxyribonucleic Acid and Multiplication of T_2 Phage

It is known that the different acridine derivatives are able to become bound to isolated nucleic acids[1]. The compounds are more strongly bound by the highly polymerized deoxyribonucleic acid than by the ribonucleic acid[1]. The results of studying the interactions with deoxyribonucleic acid and the strong antibacterial effects of nitroacridine[2] suggest that these compounds may be used as virus chemotherapeutic agents.

The purpose of this work was to obtain information about the mode of action of nitroacridines. We used *Escherichia coli* strain *B* and phage T_2, employing the standard phage methods. The nitroacridine 3663 used was described by Schnitzer[2].

Bacteria were grown at 37° C. to a concentration of 2×10^8 per ml. in 2,500 ml. M-9 medium, sedimented and infected with 5 phage per bacterium in a non-nutrient adsorption medium[3]. The infected cells were then re-sedimented and transferred to a warm M-9 medium at 2×10^8 cells per ml. (zero time) which contained various concentrations of the compound.

The phage yields were measured at time zero and at other times from 1-ml. samples, diluted into a lysing medium[4] for intracellular bacteriophage determinations.

Immediately after infection and at various times later, samples of 500 ml. were withdrawn from the culture flask and quickly poured into 50 ml. of 3 M trichloroacetic acid. The fractions of deoxyribonucleic acid of the 500-ml. samples were obtained by a modified Schmidt–Thannhauser procedure[5]. Small aliquots of the trichloroacetic acid extracts containing deoxyribonucleic acid were analysed for deoxyribose by the diphenylamine method. The bulk of the extracts of deoxyribonucleic acid were evaporated to dryness and then hydrolysed[6]. The hydrolysates were chromatographed[6] and the amounts of the 5-hydroxymethylcytosine were determined spectrophotometrically.

The growth of the *E. coli B* was measured in M-9 medium by the colony plate count and by the nephelometric method. The compound was added in various concentrations to the culture when the growth was in the logarithmic phase.

As shown in Fig. 1, nitroacridine 3663 inhibits the synthesis of infective T_2 phage similarly to proflavine[4]; at the same time it has no effect on the multiplication of the host cell. The inhibition of the phage deoxyribonucleic acid occurs only at higher acridine concentrations. The degree of inhibition agrees entirely with the host cell.

It is thus seen that the effect of nitroacridine 3663 depends on the concentration of the compound. At very low concentrations (0·05–0·15 μgm./ml.) it inhibits the synthesis of T_2 phage without inhibiting the multiplication of the host cell. To account for this phenomenon it appears that during the vegetative phase of phage development the protein and deoxyribonucleic acid parts of phage are synthesized separately by the host cell[7]. The compound is bound more strongly by the structure-free phage deoxyribonucleic acid than by the structural nucleoproteins of the host. The deoxyribonucleic acid-acridine compound formed cannot be organized into an infective phage. In other words, this compound is a decoupling agent of the synthesis of phage nucleoprotein.

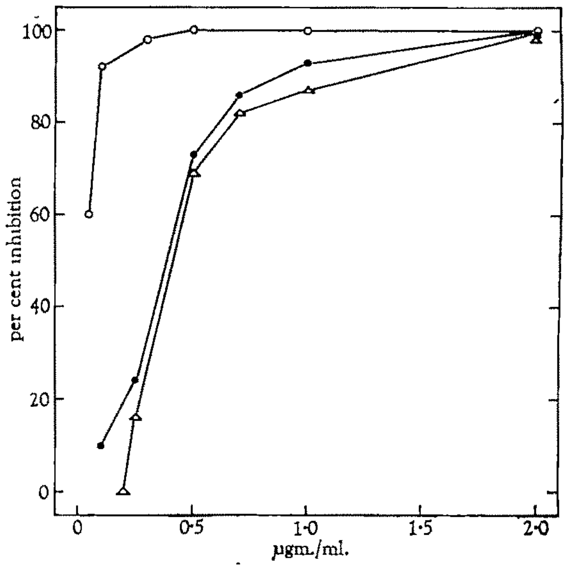

Fig. 1. Inhibitory effect of nitroacridine 3663 on —●—●—●— phage deoxyribonucleic acid synthesis (●); —○—○—○— multiplication of T_2 phage (○) and —△—△—△— multiplication of *E. coli B* (△), in per cent of untreated controls

At higher concentrations the compound inhibits the synthesis of phage deoxyribonucleic acid as well as the multiplication of *E. coli B*. The inhibitory effect is similar. From this observation it is concluded that the bacteriostatic effect of the compound is displayed by the inhibition of the synthesis of deoxyribonucleic acid.

Details of the relations of the structure and the effect of the different nitroacridines will be published elsewhere.

A Simple Test for the Presence of Metals in Biological Materials

The presence of metals in highly purified protein preparations is of considerable interest. The paramount part played by metals, especially in enzyme reactions (see, for example, ref. 1), is well known. Besides the specific metals in the metalloproteins, most proteins are able to bind, more or less firmly, metals removed from the medium. The removal of metals from a protein solution may be an important preliminary step in a study of its properties and structure. Unfortunately, the available methods for the detection of metals involve the use of very expensive equipment, or are laborious, and require large quantities of protein.

A very simple, non-specific test was devised to demonstrate the presence of metals in protein preparations. It is based on the spectral changes which occur when 8-hydroxyquinoline chelates metals. Spectral changes in the range of 300–370 mμ have already been studied[2]; but changes also occur at lower wave-lengths and have been used for this test. The alkali and alkaline earth metals give no response or a very weak one.

At neutral *p*H, 8-hydroxyquinoline has a very sharp absorption peak at 239 mμ which is shifted when chelation occurs to between 250 and 255 mμ, according to the metal involved (Fig. 1). The absorption here is approximately ten times that reported in the region of 360 mμ. It is fortunate for the effectiveness of the test that in this region of the spectrum most proteins have a minimal absorption.

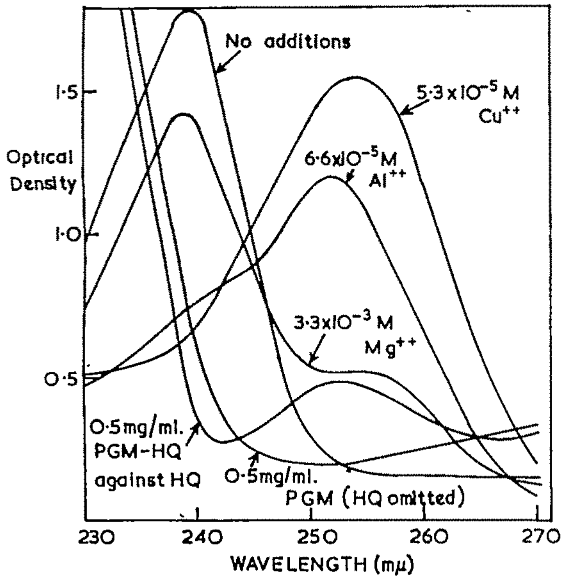

Fig. 1. Spectra of 8-hydroxyquinoline chelates. *Tris* *p*H 7·5, 8·3 millimolar; 8-hydroxyquinoline, 5·0 × 10^{-5} molar. Final volume 3·0 ml.

The general procedure for the test was as follows: The absorption of the protein (1 mgm. or less) in 1·0 ml. of 3·0 m*M* *tris*-chloride buffer *p*H 7·5 (the ionic strength was found not to be critical, stronger buffer can be used if necessary) was measured in a 'Unicam *SP* 500' spectrophotometer at 280 and 253 mμ against the same solution with protein omitted. To both blank and sample, 0·02 ml. of 2·5 m*M* 8-hydroxyquinoline was added and a reading at 253 mμ was made after mixing.

Precautions were taken to ensure that both blank and sample contained exactly the same constituents (except for the protein solution). The same pipettes were used and special care was taken to avoid contamination during mixing. Glass-distilled water was used, and was further de-ionized when very accurate determinations were required.

Results were expressed as:

$$\Delta E_{253/\text{mgm.}} = \frac{E' - E}{[\text{prot.}]}$$

where E is the optical density of the protein solution at 253 mμ, E' the optical density of the protein–8-hydroxyquinoline mixture minus the optical density of 8-hydroxyquinoline at 253 mμ, and [prot.] represents the protein concentration in mgm./ml. calculated from the E_{280} value.

Table 1. ULTRA-VIOLET ABSORPTION CHARACTERISTICS OF SOME METAL CHELATES OF HQ

Metals	Position of the peak mμ	Calculated absorption in presence of m*M* metal ions at 253 mμ
Ca^{++} and Ba^{++}	No peak observed.	—
Mg^{++}	255	0·125
Mn^{++}	253	1·170
Zn^{++}	255	25·000
Cu^{++}	254	57·200
Al^{+++}	251	17·200

HQ test as indicated in the text, but without protein. Sulphates of zinc, copper and aluminium, and the chlorides of the other metals were used.

In general the reaction was instantaneous; but in some cases the maximum absorption value was reached more slowly. The position of the peak varies slightly according to the metal as shown in Table 1, which also gives the calculated values of the optical densities for millimolar concentrations of some metals. Insolubility of the complexes was not found to be a problem, due to the very dilute solutions used, but at higher concentrations the optical density decreased after standing for a few minutes.

The test was applied to a crystalline phosphoglucomutase preparation[3], using between 0·3 and 0·8 mgm. protein per test. Phosphoglucomutase dialysed for 24 hours against large volumes of glass-distilled water gave a $\Delta E_{253/\text{mgm.}}$ value of 0·560 (Fig. 1). (From Table 1 a $\Delta E_{253/\text{mgm.}}$ value of 0·040 would correspond, for example, to about 0·06 mole of Cu^{++}, 0·2 mole of Zn^{++} or 2 mole of Mn^{++} per mole of enzyme (mol. wt. 74,000).) Passing this enzyme preparation through a carboxylic resin reduced the $\Delta E_{253/\text{mgm.}}$ to a negligible value, whereas dialysis against ethylenediaminetetraacetic acid, followed by exhaustive dialysis against glass-distilled water, increased this value.

The test was also used to follow the purification of phosvitin, which is known to contain iron, magnesium and calcium[5]. In this case the original $\Delta E_{253/\text{mgm.}}$ of 0·210 decreased to a negligible value after dialysis against ethylenediaminetetraacetic acid followed by extensive dialysis against water[6].

The test may also be applied to other materials provided that their absorption, at the wave-length used, is not too high. It proved very useful in showing metal contamination of one sample of glucose-1-phosphate which gave anomalous results when metal activation of phosphoglucomutase was studied. After passing the substrate through a sulphonic resin this anomaly was removed.

The 253 mμ peak was also used instead of the 360 mμ one in the determination of dissociation constants according to Burton[7] and for quantitative estimation of copper in pure solutions[4].

This work was carried out during the tenure of a scholarship awarded by the British Council, while on leave from the Instituto Nacional de Microbiologia, Buenos Aires. I am grateful to Dr. Malcolm Dixon for his advice.

ANIMAL PHYSIOLOGY

Comparative Adenylic Acid Deaminase Activity in Choroid Plexus and Ciliary Process Tissue

ANALOGIES between the ciliary process production of aqueous humour and the choroid plexus production of cerebrospinal fluid have been reviewed quite extensively by Davson[1]. The presence of an adenosine triphosphate-activated 5-adenylic acid deaminase in purified preparations of hog and rabbit ciliary process tissue[2,3] led to an interest in a similar system that might be present in choroid plexus tissue. It has, in fact, been shown by other investigators that 5-adenylic acid deaminase activity is present in preparations of whole dog brain[4,5].

Analytical methods employed in this investigation were as reported previously[2]. Incubations were done under the conditions described in Table 1.

Table 1. DEAMINASE ACTIVITY IN WHOLE-TISSUE HOMOGENATES
μMoles recovered after 40 min. incubation

Enzyme source	ATP	ADP	AMP	IMP	Adenosine	Total	μMoles NH_3
Dog choroid plexus	4 44	2·20	1 64	0 70	6·03	15 01	0·76
Hog ciliary processes	4 10	4·03	2 94	2·78	—	13 85	3·83

All vessels contained: 0 03 *M tris*-0 03 *M* succinate buffer, *p*H 7·4, 3 8 per cent fresh whole tissue homogenate; 7 μmoles each adenosine triphosphate and adenylic acid; 0 004 *M* magnesium chloride; 0·005 *M* potassium chloride; 0·025 *M* sodium chloride.

ATP, adenosine triphosphate; ADP, adenosine diphosphate; AMP, adenylic acid; IMP, inosinic acid.

Although the results indicate that choroid plexus tissue does have an active deaminase system, it is clear from the nucleotide recovery data that there are differences in the metabolic exchanges in the two types of tissue studied. We cannot as yet preclude the possibility that ammonia accumulation in the choroid plexus system could have resulted from deamination of any of the adenine derivatives recovered. The stoichiometry between the ammonia produced and inosinic acid accumulated is, however, strongly suggestive of the ammonia yield being the result of 5-adenylic acid deamination.

The fact that ammonia production in the ciliary process preparation was 5 times greater than in the choroid plexus preparation makes one question the activating influence of adenosine triphosphate as a deaminase co-factor in the latter tissue. This co-factor role of adenosine triphosphate has been reported for purified ciliary process preparations[6].

It has been shown previously that the deaminase of ciliary process is specific for 5-adenylic acid[2]. A similar specificity is seen in preparations of choroid plexus incubated under the same conditions described in Table 1 except substituting 14 μmoles of 3-adenylic acid as the nucleotide addition in some vessels and 14 μmoles of 5-adenylic acid as the nucleotide addition in other vessels. A yield of 0·2 μmole of ammonia was seen in the former case and 1·2 μmoles of ammonia in the latter—a 6-fold increase in activity with 5-adenylic acid.

Precise functional evaluation of the roles of these deaminase systems as regards actual aqueous humour and cerebrospinal fluid production must await further investigation. A role of adenine nucleotides in regulation of blood vessel patency[7,8] and roles of adenylic acid in many areas of metabolic interactions[9], either of which could invoke the need of an adenylic acid concentration-regulating deaminase, have already been suggested by others.

This study was supported in part by Research Grant *B*-121 from the National Institute of Neurological Diseases and Blindness, National Institutes of Health.

Effect of Kinetin on Glucose Metabolism of Chicken Embryo Fibroblasts

KINETIN, a potent plant-growth hormone, was recently discovered and identified as 6-(furfurylamino) purine, by Miller and Skoog[1]. Orr and McSwain[2] found that kinetin, at rather low levels (0·015–0·06 μgm./ml.), stimulated growth of human tissue culture.

In the course of a study of the effect of various hormones on cultures of chick embryo fibroblasts[3,4], it was observed that graded amounts of kinetin within the range of 12–24 μgm./ml. produced a roughly linear increase of total glucose consumption and lactic acid production (Fig. 1).

The ratio between glucose and lactic acid was similar in hormone-treated and control cultures. A kinetin concentration which stimulated glucose metabolism caused only slight growth inhibition. Microscopic examination revealed no abnormalities in the morphological appearance of the cells grown in the presence of the hormone.

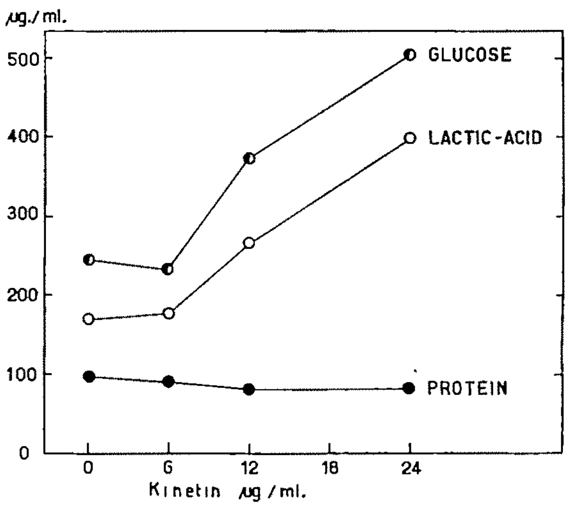

Fig. 1. The effect of kinetin on growth and glucose uptake of chick embryo fibroblasts and their lactic acid production. Procedures for cell cultivation and analytical methods were similar to those previously described (refs. 3 and 4). Cultures were incubated with hormone for 3 days prior to examination

In order to test the specificity of kinetin, a number of purines and pyrimidines and their derivatives were examined. Adenine and guanine showed a moderate and rather variable and irregular degree of stimulation; adenosine, guanosine, hypoxanthine, xanthine, cytosine, uracil and thymine did not affect glucose metabolism at a concentration up to 25 μgm./ml. Indoleacetic acid, another plant growth hormone known to affect the action of kinetin in plant tissues[5], did not modify the response of chick fibroblasts to kinetin, at a concentration up to 25 μgm./ml.

From the available data no conclusion can be drawn as to whether or not the described effect bears any relationship to the growth-promoting activity of kinetin in plants. The striking disparity between the effective levels in the two systems would rather indicate that the two phenomena are of an essentially different nature. It is not unlikely, however, that the quantitative difference is due to permeability factors.

Urinary Hyaluronidase

Ginetzinsky recently described a relationship between urinary hyaluronidase and urine concentration[1]. He found that urinary hyaluronidase assayed by his method was high at low urine volumes, virtually disappearing during water diuresis; but it remained high during an osmotic diuresis. From these results he inferred that antidiuretic hormone might act by stimulating the production of hyaluronidase within the nephron; this would facilitate water re-absorption by allowing water to pass through the ground substance between the cells. In an attempt to confirm Ginetzinsky's findings it became clear that his method[2] is unsuitable for quantitative assay of urinary hyaluronidase for the following reasons:

(1) Precise estimation of hyaluronidase by any viscosimetric method is dependent on a constant electrolyte composition of the hyaluronidase–hyaluronic acid system, as was demonstrated in 1940 by Madinaveitia and Quibell[3], and by McLean and Hale[4]. Urine has a variable electrolytic composition, and as Ginetzinsky does not appear to make any correction for this, his results are not quantitative.

(2) Ginetzinsky[1] fails to express his results as hyaluronidase excreted per minute, relying solely on arbitrary units per ml. If hyaluronidase were excreted at a constant rate like creatinine, then a graph of its concentration against urine flow per minute would be similar to Ginetzinsky's Fig. 1.

(3) He measures the initial viscosity of the mixture of urine, buffer and hyaluronic acid, the measurement being repeated after twenty minutes incubation, and the per cent reduction in viscosity is expressed as arbitrary units. This procedure is open to error as there is a rapid fall in viscosity before the initial reading[3] if a high concentration of hyaluronidase is present.

The method has been modified to allow for these factors. A detailed account will appear elsewhere, together with the results; but in principle the following changes have been made in the method of McLean and Hale[4]:

(1) The electrical conductivity of the urine is determined and compared with sodium chloride standards, the conductivity being brought to a value equal to that of 0·1 *M* sodium chloride in the final system by addition of a mixture of molar sodium and potassium chlorides.

(2) A micro-Ostwald viscosimeter is calibrated with a standard hyaluronidase preparation, incubation being at 37°C. The hyaluronidase concentration of the urine is obtained by reference to the calibration curve, and converted to units excreted per minute.

The experimental conditions chosen were water diuresis and mannitol osmotic diuresis as employed by Ginetzinsky: in addition, observations were made during potassium diuresis.

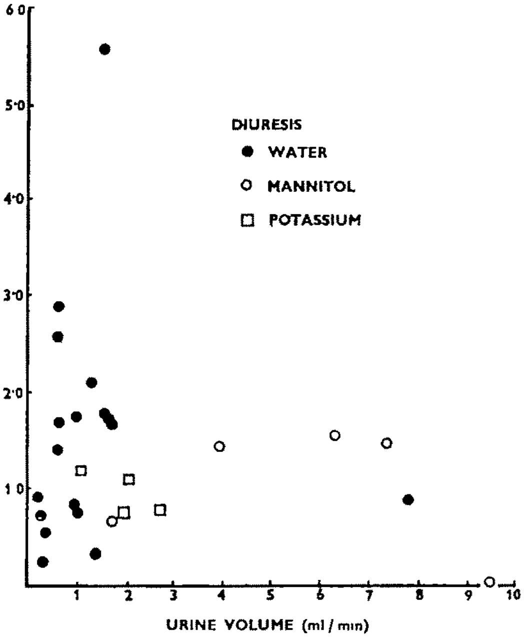

Fig. 1. Relationship of hyaluronidase output per minute to urine volume. There is no correlation between hyaluronidase excretion and urine minute volume in water diuresis or deprivation;

The results obtained demonstrate that first there is no relationship between hyaluronidase output (units per minute) and urine flow (ml. per min.) (Fig. 1). Secondly, there is in conditions of water deprivation and diuresis only an apparent relationship between hyaluronidase output and urinary osmolar excretion, sodium excretion and potassium excretion, the last three being interrelated. In osmotic diuresis in man with 25 per cent mannitol, hyaluronidase excretion remained at a fairly constant low level, in contrast to the findings of Ginetzinsky. If hyaluronidase concentration is plotted against urine minute volume (see Ginetzinsky's Fig. 2, ref. 2) there would naturally be a decrease in concentration as urine flow increases. Hyaluronidase excretion and potassium excretion both remain constant and are not related to sodium or osmolar excretion in an osmotic diuresis. In view of the constancy of potassium and hyaluronidase output in osmotic diuresis, the effect of a potassium diuresis on hyaluronidase output was observed. However, it was found that despite a rise in potassium excretion to 320 µequiv. per minute, there was no corresponding increase in urinary hyaluronidase.

Thus it is concluded that the mechanism of hyaluronidase excretion per minute is not directly related either to urine volume or to the excretion of sodium, potassium or total osmotically active solute.

Effect of Antihistamines on Mitochondrial Swelling and Liver Injury

Gallagher, Gupta, Judah and Rees[1] showed that thioacetamide, a liver carcinogen, would cause liver necrosis in rats and that a variety of antihistamines would afford protection. It was concluded that thioacetamide acted at the cell surface, but its mode of action was obscure, especially as no *in vitro* effect could be obtained. It has now proved possible to show an *in vitro* action of this compound. Liver slices, cut in the conventional manner from the livers of normal rats of the Wistar strain, show a gradual loss of certain dehydrogenases when suspended in saline solutions. Thioacetamide greatly increases this loss. Malic dehydrogenase was chosen as a suitable test system. The loss of this enzyme is shown in Table 1, which illustrates a typical experiment in the untreated slice. The effect of thioacetamide at a concentration of 0·02 *M* is shown and it can also be shown at concentrations of 5×10^{-3} *M*. These concentrations are in reasonable accord with the doses employed by Gallagher *et al.*[1], that is, 200 mgm./kgm., when it is remembered that extracellular water is of the order of 16 per cent and assuming uniform distribution of the drug.

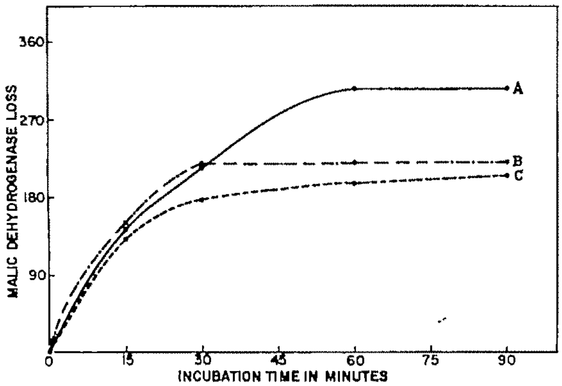

Fig. 1. Malic dehydrogenase activity was measured in the supernatant Ringer solution in which slices (about 150 mgm. wet wt.) were suspended. Samples were withdrawn as indicated and activity determined by following reduction of diphosphopyridine nucleotide spectrophotometrically. Temperature was 38°. Gas phase 95 per cent oxygen–5 per cent carbon dioxide. Dehydrogenase activity is shown in arbitrary units on the ordinates. Curve *A*, 0·02 *M* thioacetamide with calcium ion concentration 3×10^{-3} *M*; curve *B*, 0·02 *M* thioacetamide with calcium ion concentration 2×10^{-3} *M*; curve *C*, controls at both calcium-levels

The calcium-level of the medium is of importance in this action. Fig. 1 shows that reduction of the calcium-level from 3×10^{-3} *M* to 2×10^{-3} *M* results in a considerable diminution of the effect of thioacetamide. It will be seen that at both levels of calcium, the initial rates are the same but that after 30 min. the loss at the lower level is reduced to the control rate. The latter is relatively unaffected at either calcium-level. It may be inferred from this experiment that the effect of the calcium is concerned not with the initial attack of the thioacetamide, but with some subsequent step which is 'activated' by calcium, and which promotes the loss of intracellular components.

Table 1. Effect of Phenergan on Loss of Malic Dehydrogenase

Compound and concentration	Activity of malic dehydrogenase in medium as µmoles DPN reduced/100 mgm./hr. after 90 min. incubation
Nil	28·0
Thioacetamide, 0 02 *M*	40 0
Phenergan 10^{-4} *M*	24·0
Thioacetamide 0 02 *M* and phenergan 10^{-4} *M*	22 0

Liver slices (about 120 mgm. wet weight) were suspended in Krebs–Ringer, 5 0 ml., containing 0 01 *M* sodium bicarbonate with gas phase 95 per cent oxygen–5 per cent carbon dioxide. Temp. 38°. Total malic dehydrogenase activity of liver was 500 µmoles diphosphopyridine nucleotide reduced/100 mgm. liver/hr.

This interpretation is borne out by the experiments also shown in Table 1, where it will be seen that the phenothiazine antihistamine, phenergan, abolishes the effect of thioacetamide at a concentration of 10^{-4} *M*. The closely related compound chlorpromazine fails to protect these systems. Dawkins, Judah and Rees[2] have shown that phenergan prevents the accumulation of calcium in isolated perfused liver, and it may, therefore, be concluded that the action of phenergan on thioacetamide-induced leakage of malic dehydrogenase is not upon the initial attack of the drug, but upon the subsequent, calcium-'activated' step. This may also be inferred from the fact that phenergan at 10^{-4} *M* does not influence the normal rate of leakage of malic dehydrogenase from liver slices, a rate which is also uninfluenced by the calcium-levels tested, under the conditions of these experiments, but not necessarily under all conditions.

All the experiments cited above were performed in Ringer solutions buffered with sodium bicarbonate. If phosphate buffer is used at a concentration of 0·01 *M*, the action of thioacetamide on malic dehydrogenase is abolished. However, the initial attack of the drug may still be shown by following the leakage of total protein from the slices. Table 2 shows that even in phosphate buffer, loss of protein is accelerated by thioacetamide, and that this loss is unaffected by phenergan. Also shown in Table 2 is an experiment in which sodium bicarbonate is the buffer. It may be observed that a considerably greater loss of protein occurs in these circumstances and that phenergan exerts some effect. These

Table 2. Loss of Protein from Liver Slices

Compound and concentration	Mgm. protein in medium after 60 min. incubation	
	$NaHCO_3$	Phosphate buffer
Nil	5 0	3·6
Thioacetamide 0 02 *M*	8·2	5 8
Thioacetamide and phenergan 2×10^{-4} *M*	7 7	6 0
Thioacetamide and phenergan 4×10^{-4} *M*	7 3	—
Phenergan 2×10^{-4} *M*	6·3	3·5
Phenergan 4×10^{-4} *M*	6·[illegible]	—

The conditions were as in Table 1 for the experiments in sodium bicarbonate buffer; in the other experiments, phosphate buffer was added to 0·01 *M*, *p*H 7 2.

Table 3. ANTIHISTAMINES AND MITOCHONDRIAL SWELLINGS

System	Change in optical density in: 5 min.	10 min.	15 min.
Control	0·06	0·14	0·19
Phenergan 10^{-4} *M*	Nil	Nil	0·01
Benadryl 10^{-4} *M*	Nil	Nil	Nil
Pyribenzamine 10^{-4} *M*	Nil	0·03	0·03
Hispril 10^{-4} *M*	Nil	Nil	Nil

Mitochondria were suspended in 5·0 ml. 0·27 *M* sucrose–0·02 *M tris* buffer *p*H 7·2. The suspension was such that the initial reading was approximately 0·6. The changes were followed at 520 mμ on a Zeiss *PMQ*II spectrophotometer.

experiments support the hypothesis that after an initial attack by thioacetamide some degradative system is set into action. This is apparently dependent upon calcium ions and is inhibited by phenergan.

The nature of the initial attack of thioacetamide is under investigation and will be reported upon in the future. The nature of the degradative system is indicated by experiments shown in Table 3 demonstrating that several antihistamine compounds inhibit swelling of isolated rat liver mitochondria. They also protect these particles against the action of calcium ions, of hypotonic solutions and of thyroxine. They do so in concentrations and conditions in which they have no effect on respiration or phosphorylation of rat liver mitochondria, and it seems clear that they inhibit some mechanism by which isolated mitochondria accumulate water. In view of the demonstration in this work that thioacetamide action on isolated liver slices is dependent upon calcium ions and that its effect is due to a primary attack followed by a degradative reaction, it is tempting to believe that the latter is in fact the swelling and disruption of the mitochondria and that this is responsible for the liver damage caused by thioacetamide *in vivo*, which is also prevented by antihistaminics. In support of this view, thioacetamide does not affect mitochondrial swelling in cell-free preparations.

The results might also indicate a general mechanism for the action of the antihistamine compounds: it could be that all permeability changes are dependent upon mitochondrial changes, and that it is these which are prevented by the drugs in any event. Histamine then would merely trigger off the change in susceptible cells, for which it is specific, as thioacetamide is for the liver.

The actions of the antihistamines will be reported in detail shortly.

Respiration of Decapitated Mosquitoes

THE study of the basal metabolism of mosquitoes is rendered difficult because outbursts of locomotory activity may increase the respiration many-fold. Flight increases the oxygen uptake of insects 50–100 times as compared to resting rates[1] and causes variations in respiration between different groups of mosquitoes of the same strain.

We tried to eliminate the part of respiration due to locomotory activity in females of *Aedes ægypti* L. by decapitation. Decapitated mosquitoes are entirely inactive (unless purposely stimulated), but are able to survive for more than 24 hr. if kept at room temperature at a very humid atmosphere. We also measured the respiration of female mosquitoes after removal of their halteres, as haltereless mosquitoes retain some of their activity, but flight is limited to very short periods.

The respiration of intact, haltereless and decapitated mosquitoes, was measured in a Warburg apparatus at 28° C., using 10 females per cup. Readings were taken every 15 min. for 2 hr.

The oxygen consumption of decapitated mosquitoes was close to that of intact insects and much higher than that of the haltereless ones (Table 1). This observation seemed rather surprising, since haltereless insects are more mobile than decapitated ones; we suspected that the wound created by decapitation may have increased the gas exchange. When, however, the cuts were sealed with silicone grease, the respiration of the decapitated insects did not change at all.

Table 1. OXYGEN UPTAKE OF *Aedes ægypti* FEMALES

	No. of mosquitoes used	Oxygen uptake (mm.^{3}/hr./mosquito)
Intact mosquitoes	90	13·1±1·7*
Haltereless mosquitoes	190	8·2±0·6
Decapitated mosquitoes	190	14·7±0·9

* Standard error of the mean.

The effect of decapitation on the oxygen consumption is even better demonstrated at 12° C. At this temperature the intact insects are as immobile as the decapitated ones, and oxygen uptakes were 0·96 and 1·84 mm.^{3}/hr./mosquito respectively. The respiration of decapitated mosquitoes is quite steady, whereas intact insects and to a lesser extent haltereless insects exhibit variations due to bursts of activity.

Only 4–5 hr. after decapitation, the respiration of the insects begins to decrease; at the end of 24 hr. it is roughly equal to the respiration of haltereless insects.

Mosquitoes which were given a blood-feed 24 hr. prior to decapitation showed a much higher oxygen uptake than decapitated insects kept previously on a sugar–water diet (17 mm.^{3} and 11·4 mm.^{3}/hr./mosquito, respectively). Mosquitoes kept for 16 hr. prior to decapitation on a diet of water without sugar showed the same rate of respiration as those kept on sugar–water. Decapitation had no influence on the respiratory quotient, which was always between 0·9 and 1·1. In inactive intact mosquitoes, the spiracles are closed most of the time. Within a minute after decapitation the average spiracle aperture increases. Decapitation did not disturb the rhythm of the opening and closing of the spiracles. In mosquitoes which were decapitated while their spiracles were thus pulsating, the pulsation continued at the same rhythm, but the spiracles did not close completely. There was no increase in the ventilatory movements.

The corpora allata, which are known to influence oxygen consumption[2,3], are not removed by decapitation, but an inhibitory centre located in the head may be responsible for the increased oxygen uptake.

This increase in oxygen uptake as a result of decapitation was not observed with other insects. Raffy[4] reported that the oxygen uptake of adult silkworms decreased after decapitation, and I observed a similar effect with *Musca vicina* (Macq.) (Table 2).

Table 2. OXYGEN UPTAKE BY *Musca vicina*

	Oxygen uptake (mm.^{3}/hr./fly)
Intact flies	59
Haltereless flies	28
Decapitated flies	14

Decapitated and intact mosquitoes respond similarly to a reduction of the oxygen tension. The experiments were again carried out in a Warburg apparatus. In all cases the total pressure was maintained at one atmosphere by replacing oxygen by nitrogen.

Both groups maintained a nearly constant uptake of oxygen even in an atmosphere containing only 3–4 per cent of oxygen. The regulation of oxygen uptake at lower oxygen tensions is achieved in mosquitoes by changes in the spiracular activity. The spiracles control oxygen uptake by staying open for longer periods, by general enlargement of the aperture, and by increasing the frequency of opening. All three phenomena were observed in decapitated mosquitoes.

I acknowledge the helpful advice of Dr. G. Fraenkel, Urbana, Ill., and technical assistance of Mrs. Hanna Jordan.

A Method of controlling the Temperature of Insect Neurosecretory Cells *in situ*

Periplaneta americana, like many other animals, can maintain a 24-hr. rhythm of locomotor activity when in constant conditions of light and temperature. A secretion produced by the neurosecretory cells in the sub-œsophageal ganglion has been shown to act as a controlling factor in the regulation of the phases of this rhythm[1]. Chilling cockroaches at 3° C. for some hours causes the phases of the activity rhythm to be retarded, in relation to solar time, by the number of hours for which the temperature is lowered. A method has now been devised whereby the temperature of the neurosecretory cells of the sub-œsophageal ganglion can be maintained at 3° C., while the rest of the body remains at room temperature. Neurosecretion apparently ceases at 3° C., and the phases of the neurosecretory cycle are retarded by the number of hours for which the cells have been chilled.

Since many functions of insects are known to be affected by the activity of neurosecretory cells, this method of temperature control may be of interest to other workers.

The apparatus is shown in Fig. 1. A copper bar is cooled at one end by a small vessel filled with cold alcohol. At the other end is a hollow conical tip carrying the cooling point, a 0·4-mm. copper wire. This wire is part of a copper constantin measurement thermocouple and is coated with polystyrene. Within the hollow tip is a thermistor. By means of an electronic unit[2] the thermistor controls the current through the heater attached to the bar, and maintains the tip at a constant temperature which is higher than equilibrium value. The alcohol is held at a low temperature by thermal circulation from a sealed chamber immersed in an ice and salt mixture and contained in a lagged tank. The separation of this primary cooler from mechanical contact with the rest of the device allows the bar to be mounted on a manipulator, and the position of the tip to be adjusted with precision.

Demonstration of Serum Precipitin to Brain Ganglioside

STUDIES on the structure of brain ganglioside, a macromolecular glycolipid which occurs in high concentration in cerebral grey matter, suggested that this material might be suited to function at membrane surfaces, since it possesses both carbohydrate and lipid moieties structurally so arranged that the molecule could bridge hydrophylic and lipophylic phases[1]. Further investigation of the properties of this substance[2,3] demonstrated that it interacted with certain viruses, both *in vitro* and *in vivo*, in a manner suggesting that it is utilized by infecting viruses as a natural receptor substance in the cell. In a membrane-active system, the clam heart, it was found to have stimulatory effect in very low concentration[4]. The presence of hexosamine and hexose constituents in brain ganglioside relates it structurally to the blood group substances[5]. For these reasons it became of interest to determine whether antisera might be prepared to brain ganglioside.

Since this preparation of brain ganglioside does not contain amino-acid or protein components, adjuvants might have been used in initial immunization attempts. However, it was decided to attempt to obtain an antibody response to the pure substance. Rabbits were injected at weekly and monthly intervals with 0·5 mgm. of bovine brain ganglioside salt in physiological saline, the first injections being made in the toe pads of the animal, and subsequent injections being made intravenously. The presence of antibody in rabbit serum was determined by collecting blood by free drip from the marginal vein of the ear,

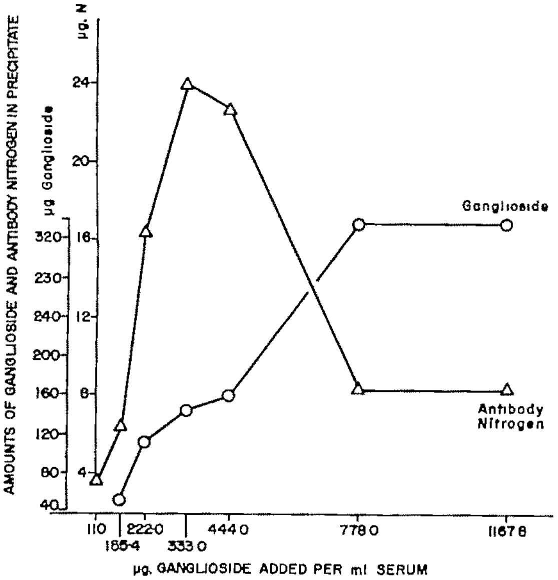

Fig. 1. Amounts of antibody nitrogen and brain ganglioside in the precipitate in the quantitative precipitin test

separating the serum, and determining the precipitin by means of the quantitative precipitin test described by Kabat[6]. The nitrogen in the precipitate was quantitatively determined by means of a Nessler's method[1]. Fig. 1 shows the results of a representative quantitative precipitin determination. In approximately one-half of the rabbits studied there was present a small amount of precipitin prior to immunization. The amount of precipitin in the serum could be increased by means of repeated injections of brain ganglioside. It may be noted that the peak of the precipitation curve is quite sharp. Because of the presence of neuraminic acid to the extent of 30 per cent by weight of the ganglioside, it was possible, by determining the neuraminic acid content, to determine the fate of ganglioside in both supernate and precipitate and thus to obtain some idea of the valence aspects of the precipitation phenomenon. The quantities in Fig. 1 are uncorrected for solubility of specific precipitate. In the zone of antibody excess, about 50 per cent of the added ganglioside is precipitated, suggesting that there is more than one immunologically distinct component in this preparation of brain ganglioside. With increasing amounts of ganglioside (into the zone of antigen excess) the precipitate contains decreasing amounts of antibody and increasing amounts of ganglioside. At the peak of the zone of maximum precipitation of antibody the precipitate contains approximately equal weights of brain ganglioside and antibody protein.

The antisera thus obtained have been used with the fluorescent antibody technique[7] to demonstrate the nerve cell body localization of brain ganglioside in bovine brain[10]. This method thus should be applicable to the histological localization of any normal or abnormal brain constituent to which antisera can be prepared.

The presence of a precipitin for brain ganglioside in mammalian serum, the titre of which is increased by successive injections of ganglioside, relates this normal brain constituent to other somatic or cellular antigens and blood-group substances immunologically as well as structurally. Other experiments in this laboratory[1-4] which have pointed to the likely membrane, transport, and receptor function of brain ganglioside are of interest in this regard. It may be that these antigenic and membrane roles are pertinently related in a manner which suggests the general function of the cellular substances which contain hexosamine or derivatives thereof (for example, muramic acid[8,9] and neuraminic acid). This function is here postulated to be the maintenance of the structural integrity and individuality of the specific cell in which they reside by the fact that their physico-chemical interaction with other molecules determines which enter and which leave the cell. Such function would have relevance to diverse biological phenomena.

These studies have been supported by grant *B*-1616 from the U.S. Public Health Service.

PLANT PHYSIOLOGY

Survival of the Twig of Woody Plants at −196° C.

I HAVE succeeded[1] in keeping alive living materials from the cell interiors of which all the easily freezable water was drawn by sufficient extra-cellular freezing at −30° C., after immersion in liquid nitrogen.

For the purpose of dehydration in various degrees, pieces from the same twig of a mulberry tree (2 cm. in length, 0·8 cm. in diameter) were pre-frozen for 16 hr. at 0°, −10°, −20°, −25°, *c.* −30° and *c.* −70° C. respectively and then immersed in liquid nitrogen. After being kept there for 10 min. they were held in air at −30° C. for 4 hr. and then transferred into air at 0° C. After this treatment the survival value of the parenchyma cells in the cortex of the twig was determined by the usual plasmolysis test. The percentage survival obtained in each case was as follows: 0 in the case of the pre-freezing at 0°, 10 at −10°, 40 to 60 at −20°, 60 to 70 at −25° and 100 at −30° to −70°. Further, in order to examine the the effect of repeated cooling, the same pieces of twig, after pre-freezing at −30° C., were immersed in liquid nitrogen for 10 min. and then were held in air at −30° C. for 1 hr. Such a process was repeated five times; but the living values were never lowered. These results indicate that if the twigs are previously frozen at −30° C., fatal intracellular freezing will never occur even at an extremely low temperature.

The same pieces of twig, after pre-freezing at −30° C., was held in liquid nitrogen for various periods of 10 min.–160 days, and the relation between the length of the immersing period and the proportion of survival was investigated. As a result of this experiment very long immersion in liquid nitrogen for 160 days at least was found to bring about no harmful effect on the plasmolysis capacity of the parenchyma cells of the twig. In addition, a twig of a willow (*Salix koriyanagi kimura*) and a piece of twig of mulberry tree in winter were not injured even when they were cooled down from room temperature to −90° C. under a cooling rate of 0·5° C./min. without pre-freezing and were maintained at −90° to −96° C. for 2 hr. It follows, therefore, that hardy material can be continuously cooled from room temperature to super-low temperatures without damage, if cooling is done at a slow rate.

Twigs of a mulberry tree pre-frozen at −30° C. gradually suffered damage as a whole after thawing from a super-low temperature, because their inner-cortex, pith-ray and pith-periclinal tissue are less resistant to freezing at −30° C. than are the parenchyma cells of the cortex. The twigs of poplar (*Populus siebodi* Mig.) and willow (*Salix koriyanagi kimura*) (15 cm. in length, 0·8 cm. in diameter), which are completely resistant to freezing at −30° C., had been kept in liquid nitrogen for 24 hr. After thawing, they were planted in moist sand in a greenhouse to test the capacity for development. The twigs so treated normally put forth buds and rooted. Most of the twigs pre-frozen at −20° C. put forth their buds; but they gradually withered within 30–50 days after planting. Twigs tested with liquid oxygen pre-frozen at higher temperatures than −15° C. never showed any sign of development. All the twigs of a willow pre-frozen at −30° C. revived even after they had been kept in liquid oxygen for 90 days. After being planted in a greenhouse in March 1959, their new shoots were about 90 cm. long by June 1 and are still growing normally.

In this pre-freezing method, the percentage survival is scarcely affected by the rate of cooling to and re-warming from a super-low temperature if the material is previously frozen at −30° C.[2]. If the living materials can withstand pre-freezing at a temperature lower than −30° C., they might be able to survive freezing at extremely low temperature by this pre-freezing method. It can be applied to materials with less frost hardiness, if any such anti-freeze agent as a glycerol is previously used on them so that freezing at −30° C. can be resisted.

Recently, Asahina[3-5] obtained some experimental results to support the view that this pre-freezing method is remarkably effective for keeping various animals alive in liquid oxygen. He kept a slug caterpillar[3], in overwintering prepupal stage, alive in liquid oxygen, the gill pieces of the oyster (glycerin used), overwintering larvæ of a butterfly, and a plant-parasitic nematode after pre-freezing at −30° C. Nei[6] kept yeast cells, suspended in distilled water, alive in liquid nitrogen, after a pre-freezing as low as −30° C.

From these facts it seems that there is a definite temperature at which almost all the easily freezable water in a cell may be drawn from the cell interior by extracellular freezing, and that the cells and tissues in this state are not injured even when exposed to an extremely low temperature. In the case of plants and animals this temperature lies around −30° C. Below this temperature, the intensity of cold seems not to exert any important effect upon woody plants, at least as long as the intense cold does not extend over a long period, and also it seems that the low temperature itself cannot be a primary factor of damage by frost.

Further details of this work will be published elsewhere.

Effect of Direction of Growth on Sultana Canes

SULTANA vines are pruned to a limited number of one-year-old shoots (canes), each of which may carry up to 20 buds. As canes vary greatly in the proportion of fruitful buds the pruner aims to retain only the more fruitful ones on the vine. Such a selection is possible because the appearance of a cane indicates to some extent its fruiting potential[1]. But it is not known why canes of comparable origin differ both in appearance and in fruitfulness.

It was thought that the orientation of the growing cane in the gravitational field could be one contributing factor. Strong gravimorphic response has been reported for shoots on fruit trees[2]. Investigations were therefore carried out during 1958–59 to test the effect of gravity on sultana shoots, particularly with respect to the fruitfulness of their buds.

For 12 sultana vines, growing in the field at the Commonwealth Research Station, Merbein, the normal trellis height of 4 ft. was increased by erecting a vertical wire netting trellis to a total height of 7 ft. 6 in. Two shoots each in the centre of each vine were directed vertically upwards (0°), and at angles diverging from this direction by 45°, 90°, and 120°. The shoots were trained in their respective positions from October 16, more than one month before the initiation of the first bunch primordia, until the beginning of January, when the development of at least the first 20 buds was completed on the shoots attaining that length.

In June the length of all the shoots which had matured at least three buds was measured and the number of mature buds counted. All buds to position 20 were microscopically examined for the presence of bunch primordia which were extracted and weighed on an electro-balance. The results are shown in Table 1.

In fruit trees horizontal shoots grow less and form more flowers than vertical shoots[2]. This does not apply in the sultana where fruitfulness and bunch primordium development were severely depressed when canes were diverted from their normal direction of growth. Under natural conditions sultana shoots tend to grow vertically at least until flowering during the middle of November.

The total extension growth did not differ between the canes of the four treatments, but the canes of

Table 1. EFFECT OF DIRECTION OF GROWTH ON SULTANA CANES

	Canes deviating from the upward vertical direction by			
	0°	45°	90°	120°

Mean length of cane (cm.)	184·7	177·7	287·4	241·9
Mean internode length (cm.)	5·74	5·56	7·66	7·23*
Mean per cent fruitful buds†	39·7	44·7	17·3	20·4*
Mean bunch primordium weight (μgm.)	68·0	58·7	47·6	36·1*

* Treatments 0° and 45° differ significantly from treatments 90° and 120° in mean internode length, per cent fruitful buds, and mean bunch primordium weight.

† Statistically analysed as angular transformations.

treatments 90° and 120° had longer internodes. This could indicate that these canes were to some extent affected by being shaded for some hours daily by the rest of the vine. Heavy shading of sultana vines causes not only extension of internode length but it also reduces fruitfulness[3]. In treatments 90° and 120° bunch initiation and development may have been somewhat inhibited by the shading, but this was far too light to nullify any effect of gravimorphism such as found in fruit trees.

One could speculate that the grape vine differs from fruit trees and also from the Japanese larch[4] in its reaction to gravity because it is a climber under natural conditions. This problem may bear further investigation.

Effect of Gibberellic Acid on Seeded Grapes

Size of grape berries was found by Muller-Thurgan in 1898 to be correlated with its number of seeds[1]. Size of seedless berries could be increased by means of auxins such as *p*-chlorophenoxyacetic acid[2,3] and by gibberellin spray[4,5]. The sprays had, however, no effect on size of seeded grapes[6,7].

Bunches of 'Queen of Vinyard' grapes were sprayed about 23 days after full bloom with 20 p.p.m. α-naphthalene acetic acid and gibberellin, respectively; 0·1 per cent 'Triton *X*-100' was added as wetting agent. 'Triton' alone was used for the controls. The fruit was harvested at full maturity, weighed, cut in halves and the number of seeds determined.

Results in Table 1 show a correlation of size of fruit and number of seeds. The 20 p.p.m. α-naphthalene acetic acid had no effect on fruit size; gibberellin, on the other hand, showed a marked effect. The added weight, however, decreased with the increasing number of seeds.

Table 1. Effect of Growth Substances on Grape Berries containing Different Numbers of Seeds. (Weight of 100 Berries in gm.)

Treatment	Seed No. per berry 0	1	2	3
Control	19	349	465	523
α-Naphthalene acetic acid	81	355	457	533
Gibberellin	181	491	506	526

This decrease is shown more clearly in the ratio between the weight of treated and untreated berries as affected by number of seeds (Fig. 1). The curve indicates that while the ratio is about 2·5 with parthenocarpic fruit it approaches 1 when the number of three seeds is reached.

It can be concluded, therefore, that gibberellin has a physiological effect on seeded berries, but only to a limited extent. Gibberellin compensates for the 'lack' of seeds; but once the berry has a sufficient number of seeds, gibberellin at the concentration used had no further effect.

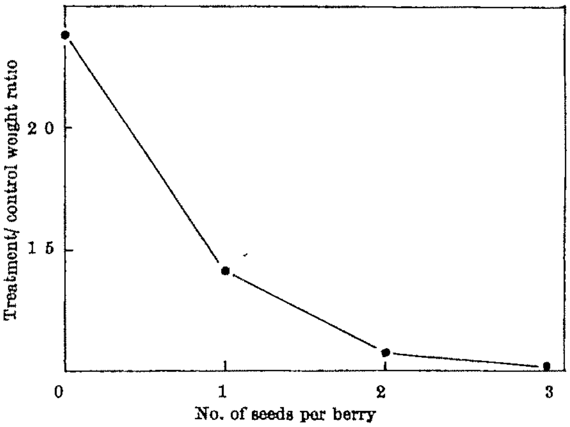

Fig. 1. Ratio between weight of gibberellin-treated and control grape berries as affected by number of seeds

No seed-like formations were found in the fruit due to gibberellin, though the tissue was more firm at the missing seed locations. α-Naphthalene acetic acid showed no effect.

Mutagenic Action of Mitomycin C on *Escherichia coli*

Mitomycin *C* is of biological interest not only because it selectively inhibits cellular deoxyribonucleic acid synthesis[1,2] but also in that it induces lambda phage development in *Escherichia coli K* 12[3].

In this communication we present evidence that mitomycin *C* also affects the genetic mechanism, such as exerting a mutagenic action and stimulating the recombination rate in *Escherichia coli*.

Mutagenic action of mitomycin *C* was demonstrated in the reversion of *Escherichia coli B/r* tryptophan-requiring strain to the wild type. Logarithmic growing cells of this strain were harvested by centrifugation and resuspended in glucose-salt medium containing mitomycin *C* at a concentration of 1 μgm./ml. and incubated at 37° for 15 min. After the agent was removed by centrifugation, a part of the treated cell suspension was plated both on nutrient medium and minimal medium in order to count the total number of viable cells and the revertants to the wild type, immediately after the treatment. Another part of the treated cell suspension was incubated in broth after the treatment and assayed by the same method after one hour incubation.

During the treatment with mitomycin *C* the total number of viable cells decreased to one-tenth of the initial but during the post-incubation in broth the number of viable cells remained constant. Immediately after the treatment with mitomycin *C* the ratio of number of prototroph colonies to the total number

Table 1. EFFECT OF MITOMYCIN *C* ON THE YIELD OF THE WILD TYPE

Exp. No.	Conc. of mitomycin *C*	Time of incubation after the treatment 0	30 min	60 min.
1	1 μgm /ml.	36*	90	77
	0	1·2	1 5	0·3
2	1 μgm /ml.	25	182	177
	0	1 8	1·9	1·3

* Number of revertants per 10^8 viable cells.

of viable cells increased about tenfold of spontaneous reversion ratio. Much increase was found in the post-incubated cells (Table 1).

The effect of mitomycin *C* on the recombination rate of *Escherichia coli K* 12 was also examined. Cells of *Escherichia coli K* 12 58–161 *F*+ methionine-requiring strain were treated with mitomycin *C* in the same way as described above. The treated *F*+ cells were crossed with cells of *Y*–70 *F* – threonine, leucine and thiamine requiring strain, immediately after the treatment or 1 hr. incubation in broth followed by the treatment.

The ratio of prototrophic recombinants to the total viable cells was also increased five- to ten-fold and a greater enhancement was confirmed in the post-incubated sample. The reciprocal treatment of the recipient *F*– cells was ineffective to increase this ratio. The question remains as to whether the donor cells which lost their ability to form colony by the treatment with mitomycin *C* retain their capability to donate their chromosome.

These effects of mitomycin *C* on *Escherichia coli* obtained here were very similar to those due to ultra-violet radiation.

We are indebted to Prof. H. Kikkawa for his suggestions and criticism, and to Dr. S. Shiba for his generous supply of mitomycin *C*. We also wish to express our appreciation of the suggestion and encouragement given by Prof. Y. Takagi in Kanazawa University. This work was supported in part by a grant from the Ministry of Education.

HÆMATOLOGY

In vitro Synthesis of Fœtal and Adult Hæmoglobin by Fœtal Hæmatopoietic Tissues

THE demonstration of a biochemical distinction between adult and fœtal forms of hæmoglobin (hæmoglobins *A* and *F*) has stimulated interest in their physiology and biochemistry[1]. Little is known about the site of origin or conditions governing the production of these two hæmoglobins. It has been postulated that hæmoglobin *A* is synthesized in the bone marrow and that hæmoglobin *F* is produced principally in the liver and spleen[2,3]. This theory corresponds well with the known sites of red cell production in the fœtus and in the adult[3]. As a corollary, it has been proposed that hæmoglobin *A* and hæmoglobin *F* occur in separate red cells[2,4]. Anoxia has been thought to increase the production of hæmoglobin *F*[4]. This report presents a study of the synthesis of hæmoglobins *A* and *F* by hæmatopoietic tissue from two white human fœtuses aged 17 and 9 weeks.

A viable fœtus of 17 weeks gestation (by menstrual history) was obtained immediately after surgical removal. Cell suspensions (approximately 100×10^6 nucleated cells per aliquot) were prepared from liver, spleen and bone marrow[5]. The cells were incubated for 24 hr. in 2 ml. of 50 per cent adult serum (type *AB*) in Hanks's solution (*p*H 7·6) containing 125 μgm. (2·7 μc.) of glycine-2-^{14}C. The percentages of oxygen in the gas phase during incubation are shown in Table 1. At the end of incubation the cells were washed three times with saline, and an excess of carrier hæmoglobin was added. The carrier contained 60 mgm. of hæmoglobin *A* and 60 mgm. of hæmoglobin *F*, prepared as a mixture of adult and cord blood. The alkali denaturation procedure[6] was used to determine the amount of hæmoglobin *F* in the cord blood. The samples were converted to carboxyhæmoglobin, and the adult and fœtal fractions were separated on an ion exchange column (1 × 10 cm.) using 'Amberlite *IRC*-50 (*XE* 64)' with a sodium citrate buffer at *p*H 6·5 as described by Prins and Huisman[7]. The separated hæmoglobins were dialysed for 48 hr. against distilled water, dried and counted at infinite thickness in a flow gas counter.

The results of the experiment are shown in Table 1. The measurements presented do not support the postulation of separate organ sites for the production of adult and fœtal hæmoglobins[2,3]. Relatively more hæmoglobin *F* was produced by cells from liver and spleen than from bone marrow, but the bone marrow of this fœtus produced twice as much hæmoglobin *F* as hæmoglobin *A*.

Anoxia did appear to induce a relative increase in the proportion of hæmoglobin *F* as compared to hæmoglobin *A*. However, it should be pointed out that the synthesis of both hæmoglobins decreased with decreasing oxygen tension.

Table 1 also shows a comparable experiment using the liver of a fœtus of 9 weeks gestation. Radioactivity indicating hæmoglobin synthesis was found both in the adult and in the fœtal fraction and in a proportion of about 1 part adult to 2 parts fœtal.

Walker and Turnbull[4] reported that hæmoglobin *A* is absent from fœtal blood until the 13th week of gestation. In the experiment shown in Table 1, hæmoglobin *A* was actively synthesized in the liver of the fœtus of 9 weeks gestation. Since synthesis of hæmoglobin *A* in hæmatopoietic cells must begin before significant amounts appear in the blood, the observations of Walker and Turnbull are not

necessarily incompatible with those here reported. At a given time the ratio of synthesis of hæmoglobin *A* to hæmoglobin *F* must be greater than the ratio of these two hæmoglobins in the blood due to the life-span of the red cells, to the increasing percentage of hæmoglobin *A* and to the expanding blood volume of the fœtus. Should fœtal red cells containing hæmoglobin *A* have a relatively shorter life-span than those containing hæmoglobin *F*, the synthetic ratio, *A*/*F*, might be even higher. However, our observations do not bear upon the question of whether separate red cells contain exclusively one or the other types of hæmoglobin[3,4].

We have assumed the presence of only two hæmoglobins, *A* and *F*. It is now generally recognized that these two fractions are heterogeneous[8]. Experiments to characterize these hæmoglobin subfractions and to evaluate their importance in hæmoglobin synthesis are in progress.

Plasma Antihæmophilic-Factor Concentrations in the Australian Aborigine and in Conditions associated with Hyperglobulinæmia

While studying the plasma antihæmophilic-factor concentrations of a large number of healthy individuals, it was noted that Australian aborigines in general have higher plasma concentrations of this factor than the white Australian population. The factor was estimated by a technique[1] based on the thromboplastin generation test and results were expressed as a percentage of the concentration in a standard normal plasma. The lower histogram in Fig. 1 shows the plasma concentrations in 86 healthy white adults adjusted to the nearest 10 per cent. The values are skewed with a fairly sharply defined lower limit and range from 60 to 200 per cent of standard normal. This group comprised equal numbers of males and females, and there was no significant sex difference in the values. These normal results are very similar to those found in a previous group of 80 normal white adults reported on from this laboratory[2].

Concurrent with the examination of this normal group, blood samples were examined from 28 Australian aborigines who were hospital in-patients.

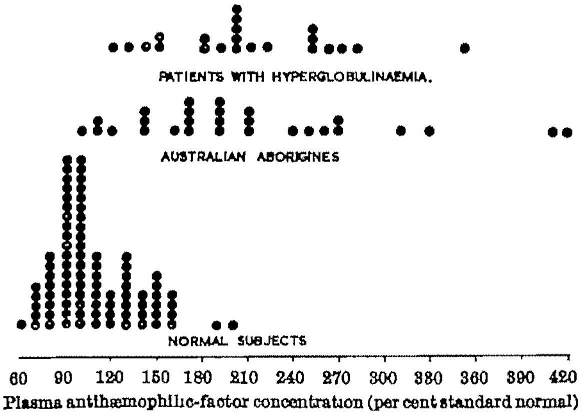

Fig. 1. Plasma antihæmophilic-factor concentrations in normal subjects, Australian aborigines and patients with hyperglobulinæmia

The plasma antihæmophilic-factor concentrations are shown in the middle histogram in Fig. 1. Values ranged from 100 to 420 per cent of standard normal and twelve samples showed values greater than the upper limit of the normal white range. The natives were of mixed purity from half caste to full blood. They were in hospital mostly for surgical or traumatic reasons. The higher values could be the result of different racial origin. However, the Australian aborigine has a higher concentration of plasma γ-globulin than the white Australian[3]. It was therefore decided to investigate white Australians who had hyperglobulinæmia as the result of disease.

The upper histogram in Fig. 1 shows the plasma antihæmophilic-factor concentrations in 22 white Australians who had hyperglobulinæmia as a result of varying diseases including lymphosarcoma, auto-immune disease, hepatic cirrhosis, nephrosis and multiple myelomatosis. Values ranged from 120 to 350 per cent of standard normal and approximated more to the aboriginal group than the white normal group. Nine samples showed values greater than the upper limit of the white normal range.

The plasma antihæmophilic-factor value is thought to be genetically determined and constant for the individual. The findings in the patients with hyperglobulinæmia indicate that the value can alter with disease. That plasma antihæmophilic-factor concentration may be related to the γ-globulin concentration is unexpected since the antihæmophilic-factor migrates electrophoretically with fibrinogen.

Absorption–Elution Grouping of Dried Blood Smears

Thick blood smears (5–10 μl./cm.^{2}) can be grouped in the ABO blood group system by an absorption-elution technique which has been evolved in this Laboratory over the past two years.

Dried blood smears, on standard microscope slides, prepared in the usual way, are fixed by plunging in *p*H 7·4 McIlvane buffer at 100° C. for 30 sec. The denatured smears are then blotted dry and divided into separate cavities bounded by gum dammar/beeswax mixture[1], the number of cavities being governed by the number of antisera to be employed. Antisera are then dispensed into the relevant cavities in excess of the amount required to saturate the antigen. The slide is allowed to stand at room temperature, in a moist chamber, for 3 hr. with occasional gentle agitation, then rinsed under the cold tap and blotted dry. Drops of 2 per cent v/v red cell suspension are next dispensed into the different cavities and the temperature of the slide is raised to 50° C. for 5 min. in a preheated moist chamber.

On removal to room temperature, and gentle rotation, agglutination of the red cells occurs in those cavities where antibodies have been eluted by the elevated temperature.

Typical results obtained are shown in Table 1.

Table 1

	Antiserum and cells added					
Group of blood smear	Anti-A A_1	Anti-A_1 A_1	Anti-B B	Group O A_1	Group O B	Gorse Anti-H O
A_1	+	+	−	+	±	−
A_2	+	−	−	+	±	+
B	−	−	+	±	+	±
O	−	−	−	−	−	+
A_1B	+	+	+	+	+	−
A_2B	+	−	+	+	+	+

+, Macroscopic agglutination; ±, variable results, −, no agglutination.

The agglutination is, in nearly all cases, visible to the unaided eye, although with some thinner blood smears microscopic examination may be necessary. Using group O antiserum, an A blood smear (especially if very thick) may elute anti-B and conversely a group B blood smear may elute anti-A. This is in agreement with the results obtained from antibody elution from intact cells[2]. Gorse extract is a source of potent and specific anti-H[3] while the anti-A_1 antiserum used is pooled group B absorbed with A_2 cells. The appearance of a slide bearing a smear of A_2 blood on completion of grouping by the above technique is shown in Fig. 1.

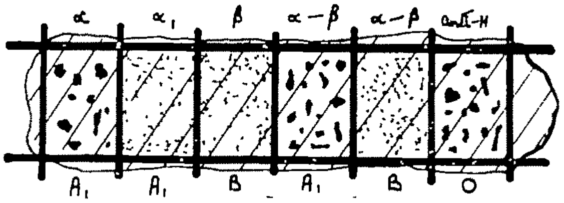

Fig. 1

The anti-A and anti-B sera used (cols. 1 and 3) have given unequivocal results in all tests we have made. The group O serum reactions (cols. 4 and 5) have given consistently weaker reactions than separate anti-A and anti-B, but we have included it as a check and as being of possible significance when testing for subgroups of A weaker than A_2. The anti-A_1 and anti-H reactions have in most cases given good reciprocal results.

The technique has obvious uses in the field of blood grouping, particularly since we have recently found that it can be applied to smears made from dried bloodstains. The advantages are that no antisera of standardized titre are required, no interference by detergents is encountered (these are extracted by the hot water) and the results can be read immediately without tedious pipetting and microscopic examination. The smears can be stored indefinitely and repeat grouping can simply be made by rinsing the cells and antibodies off the slide with water at 50° C. and starting again as with a freshly fixed blood smear.

The method shows obvious promise, and merits further investigations to an extent which is not possible in a routine laboratory. These preliminary observations are published in the hope that research workers in blood group serology will take the study further.

I am indebted to Dr. I. Dunsford for criticism, antisera and blood samples, and to Dr. I. M. Barclay, director of this Laboratory, for permission to publish this communication.

RADIOBIOLOGY

Evidence for Protein Turnover in an Embryonic System

IN a previous communication we have compared the relative efficiency of various proteins, peptides and free amino-acids as precursors of chick embryonic proteins[1]. From these studies we concluded that during the early stages of development the preferred precursor was yolk protein (rather than peptides or amino-acids) and that the pathway of synthesis of chick embryonic protein probably proceeded via a stage involving amino-acid derivatives (possibly amino acyl adenylates[2] or, more likely, amino-acids linked to the terminal adenosine residues of polyribonucleotides[3-6]).

In the present study we investigated the utilization by chick embryos of intravenously injected sulphur-labelled protein precursors in the formation of heart and liver, as well as the relative rates of growth of these organs, as indicated by the uptake of label by these organs.

Torulopsis utilis was grown on sulphate labelled with sulphur-35 according to the method of Wood and Perkinson[7]. After extraction with organic solvents[8], the yeast protein was hydrolysed with a 1:1 mixture of 6 *N* hydrochloric acid and 90 per cent formic acid. The humin was removed by centrifugation, and a portion of the neutralized hydrolysate corresponding to about 1 mc. of the original labelled sulphate per 30 gm. body-weight was injected intraperitoneally into a White Leghorn hen. In other experiments cystine labelled with sulphur-35 was removed from the yeast protein hydrolysate by adding carrier cystine, and precipitating this amino-acid at *p*H 4·5 in the cold overnight. This cystine-free yeast protein hydrolysate was then injected into baby chicks. Eight to twelve hours after injection the animals were bled by heart puncture, and serum albumin and serum albumin peptides were prepared by methods previously described[9]. Embryonated White Rock eggs were incubated at 38°C. under conditions of controlled humidity for a period of 9 days. Embryos were injected intravenously[10] with one of the following protein precursors on the ninth day of incubation: yeast protein hydrolysate containing either methionine labelled with sulphur-35 alone or containing both labelled methionine and labelled cystine; chicken serum albumin peptides containing sulphur-35 in the methionine residues or containing sulphur-35 in both the methionine and cystine residues; or chicken serum albumin containing labelled methionine. It should be pointed out that all preparations also contained some labelled methionine sulphoxide[9]. On the tenth day of incubation hearts and livers were excised[10], the organs pooled and homogenized, and dry protein powders prepared for counting[9]. The results of these experiments are shown in Table 1.

Table 1. DISTRIBUTION OF LABEL IN EMBRYONIC CHICK HEART AND LIVER ON THE TENTH DAY OF INCUBATION AFTER INTRAVENOUS INJECTION OF VARIOUS PROTEIN PRECURSORS ON THE NINTH DAY OF INCUBATION

Precursor injected	Per cent injected activity		Specific activity (Heart/Liver)
	Heart	Liver	
Yeast hydrolysate containing labelled methionine	0·62	1·61	1·30
	0·55	1·62	1·08
Yeast hydrolysate containing labelled methionine and labelled cystine	0·62	1·62	1·18
Chicken serum albumin peptides containing sulphur-35 in the methionine residues	0·55	1·66	1·23
	0·46	1·77	1·20
	0·56	1·48	1·37
Chicken serum albumin peptides containing sulphur-35 in the methionine and cystine residues	0·35	1·23	1·50
Chicken serum albumin containing labelled methionine	0·12	0·40	1·24
	0·29	0·56	1·95

The results are presented here in two ways: as the percentage of injected activity found in the two organs for each of the precursors injected, and as the ratio of specific radioactivity of heart/liver. The values indicating the percentage of injected activity are uniformly larger for liver than heart, as is expected on the basis of the difference in size of the two organs on the tenth day of development. It will be noticed, however, that all the values (independent of the type of protein precursor injected) for embryonic heart are quite close to one another, as are the values for embryonic liver.

These results indicate that while anabolism is certainly the predominant process in this rapidly proliferating system, some catabolic capacity must also be operative in order to account for the conversion of injected serum protein and peptides into embryonic tissues. This is in contrast to the finding that catabolism does not take place in rapidly growing bacterial systems[11,12], but corresponds more closely to the situation in resting bacterial suspensions where protein turnover is known to take place[13]. We had previously suggested[1] that in the conversion of yolk protein to embryonic chick protein the catabolic activity was centred in the yolk[14] while the synthetic activity resided in the embryo proper. The present results do not conflict with this conclusion but indicate that the embryonic system itself does contain a catabolic potential.

The ratio of specific radioactivity of heart/liver is also shown in Table 1 and is uniformly greater than 1·00. This indicates that both organs are capable of incorporating each of the various protein precursors tested at essentially similar rates; furthermore, over the period of the experiment the heart is anabolically more active than the liver (that is, within the time period tested a greater fraction of its newly synthesized protein has its origin in the precursors supplied).

One of us (H. R. M.) was supported by grants-in-aid from the National Heart Institute, United States Public Health Service (No. H-2177) and Eli Lilly and Co.

Ear Tumours in Rabbits receiving Strontium-90

THE induction of bone tumours by radium and other 'bone-seeking' radioactive materials is now well known. It was originally observed in human cases of radium poisoning[1-4]. Experimentally, similar tumours have been produced in a wide range of animal species following the administration of either radium[5-9] or a variety of 'bone-seeking' radioactive isotopes such as strontium-89, strontium-90, plutonium-239 and calcium-45[10-19]. Tumours occur in the neighbourhood of sites of maximum isotope deposition and retention (see ref. 13). In young rabbits receiving a single injection of strontium-90[13], tumours occurred most frequently in the metaphysial regions of the long bones, while in both old and young rabbits[20] they occurred adjacent to growing teeth in the mandible and maxilla.

Less well known are the tumours of soft tissues adjacent to bone which occasionally develop in the same circumstances. Among their cases of radium poisoning, Aub *et al.*[4] reported three examples of epidermoid carcinoma arising in the nasal accessory sinuses or in the temporal bone. Koletsky *et al.*[12] noted squamous cell carcinoma of the nasal region of rats following the administration of phosphorus-32, Kuzma and Zander[18] observed similar squamous cell carcinomas in rats following the administration of strontium-90 (but not in rats receiving calcium-45), and Finkel, Biskis and Scribner[21] have observed similar tumours in mice receiving strontium-90. The present communication directs attention to the occurrence of tumours of the epithelium of the external auditory meatus in certain groups of rabbits receiving strontium-90.

In a study of the effect of a single injection of high dose of strontium-90 (500–1,000 μc./kgm.) in rabbits[13],

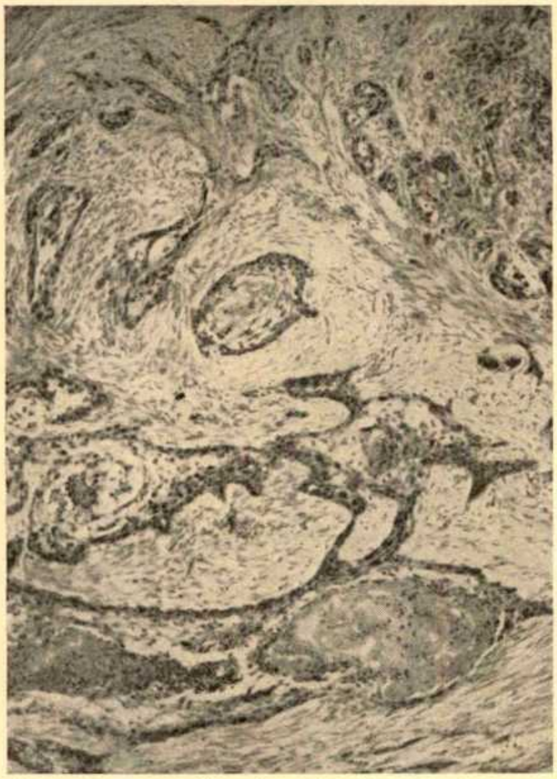

Fig. 1. Squamous cell carcinoma invading soft tissues near temporal bone. (× 66)

it was noted that three of a litter of four rabbits injected with 500 μc./kgm. at the age of 2 days developed symptoms, about 6 months later, attributed to a lesion of the vestibular apparatus. The rabbits were extremely unsteady in gait, they tended to fall over, and carried their heads on one side. Gross examination of the skull and the brain failed to show any obvious abnormalities, except that the external auditory meatus appeared to be blocked with inspissated wax. This proved sterile on culture. The skulls were unfortunately lost before histological examination was made.

A second litter of 4 new-born rabbits, injected with 500 μc./kgm. at 2 days of age, has now been studied. These rabbits all died after a period of 14–22 months: they failed to show evidence of bone damage or tumour formation in the peripheral skeleton, but they presented the same symptoms of ear disease that were noted in the first group. Examination of the external auditory meatus showed that it was occupied by a mass of friable dark wax-like material: histological examination showed the lesions to be squamous carcinomas of the external auditory meatus. In two of the rabbits, invasive squamous cell carcinomas (Fig. 1) of the external auditory meatus were present in each ear: in the remaining two, one ear showed an invasive carcinoma while the other showed a diffuse thickening of the epithelium (Fig. 2) which is regarded as a carcinoma *in situ*. The invasive tumours extended to the soft tissues surrounding the ear, the temporal bone and the cavities of the middle ear.

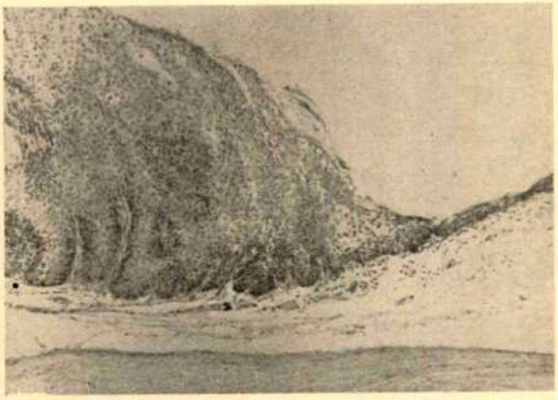

Fig. 2. Thickened (possibly carcinomatous) epithelium in external auditory meatus. (×50)

In order to determine whether epithelial tumours develop in the ears of older rabbits injected with strontium-90, we have examined histological sections from the temporal bones of two other groups of animals (Table 1). The first of these consisted of 5 rabbits injected at the age of 6–8 weeks. Three of these each received 200 μc./kgm. strontium-90 and lived for 19–27 months (908, 909, 910). In two of these animals (one of which had symptoms similar to those present in the previous groups) one ear showed an invasive squamous cell carcinoma of the external auditory meatus, while in the third the epithelium of the external auditory meatus was not abnormal. The two remaining weanling rabbits received 600 μc./kgm. strontium-90 each (802, 902). One, killed at 9 months, had an invasive squamous cell carcinoma of the external auditory meatus on one side and proliferative apparently neoplastic change on the other; the other, killed at 7 months, showed irregular and apparently neoplastic thickening of the epithelium of the external auditory meatus on each side, although no invasive tumour was present.

The second group consisted of 9 rabbits injected at the age of one year with doses of 200–1,000 μc./kgm., and dying 6–34 months later. None of these animals presented symptoms of ear disease, and in none of them were histological abnormalities of the external auditory meatus found.

Spontaneous tumours in this situation do not appear to have been reported in rabbits. It would appear likely that the tumours in the experimental animals resulted from irradiation of the epithelial tissue from strontium-90 deposited in the surrounding and immediately adjacent bone, although the changes we have regarded as carcinoma *in situ* sometimes extend to the epithelium of the outer part of the external auditory meatus at some distance from the temporal bone. In such a situation, the mechanism of tumour induction is not clear: perhaps some migration of the epithelial tissue occurs during growth and development, or the uptake and retention of strontium-90 or its decay product yttrium-90 in other tissues, such as the adjacent cartilage of the pinna, may be concerned.

It is perhaps significant that in the weanling rabbits a number of the ear tumours occurred in animals that had survived longer than others of the same series in which bone tumours had developed, and it may be that the development of malignant change in epithelial tissues adjacent to bone takes longer than in bone itself. In this connexion, it is interesting to note that 2 of the 3 epidermoid carcinomas of nasal accessory sinuses reported by Aub *et al.*[4] in human radium poisoning developed as long as 33 years after exposure to radium, while periods of 15–18 years were concerned with the 6 bone sarcomas reported in the same series.

The retention of strontium-90 and yttrium-90 in the temporal bone and the cartilage of the pinna is being studied further.

Incorporation of Tritiated Uridine into Amphibian Eggs

THE incorporation of labelled precursors into amphibian embryos is limited by the presence of a coat which covers the embryo and which renders the embryo impermeable to a large number of substances. One of them is uridine. However, we found that embryonic cells the coat of which has been disintegrated by placing them in a medium totally devoided of calcium incorporate tritiated uridine very rapidly, while the control embryos do not. Using this procedure, we have been able to follow the incorporation of this substance into dissociated embryonic cells at different stages of development.

Eggs removed at the desired stages were decapsulated. These eggs, still in their vitelline membrane, were cultivated in the following medium: sodium chloride (17 per cent), 20 ml.; potassium chloride (0·5 per cent), 10 ml.; *tris*, 560 mgm.; water, 966 ml.; *N* hydrochloric acid, 4 ml.; citrate, 5 gm.

In this medium, the embryos disaggregate into a mass of dissociated cells surrounded by the vitelline membrane.

After dissociation, the cells were replaced in the same medium without calcium, but deprived of citrate. The incorporation of uridine was followed by the autoradiographic technique of A. Ficq[1], after fixation by freeze-substitution.

At the blastula and young gastrula stages, the incorporation of tritiated uridine is exclusively nuclear. Treatment of the sections with deoxyribonuclease before application of the photographic emulsion completely removes the radioactivity: on the other hand, treatment of the sections with water or ribonuclease has no effect on the radioactivity. Therefore, uridine seems to be incorporated into deoxyribonucleic acid. This incorporation probably occurs at the level of the pyrimidine bases of deoxyribonucleic acid, because hydrolysis of the sections with *N* hydrochloric acid for 5 min. at 60° has no effect on the radioactivity. During gastrulation and neurulation, nuclear activity remains intense. A greater heterogeneity in the distribution of radioactivity among the embryonic nuclei is observed. At the same time, radioactivity becomes conspicuous in the cytoplasm. Cytochemical tests indicate a change in the nature of the substances incorporating uridine. The nuclei, in slides treated with ribonuclease or *N* hydrochloric acid at 60°, now lose about half their radioactivity. After incubation of the sections in the presence of deoxyribonuclease, 30–40 per cent of the radioactivity remains in the nuclei. It should be mentioned that all the cells do not behave in exactly the same manner when they are submitted to this treatment. At the onset of segmentation of the egg, the importance of the coat is still such that penetration of the precursor is impossible even in the presence of citrate. Unsegmented eggs incubated in the presence of uridine and citrate for about 20 hr. exhibit nuclear incorporation in the daughter cells. At this stage, the localization of the tracks is either nuclear or chromosomal.

In summary, until the neurula stage, nuclear incorporation predominates over cytoplasmic incorporation. Uridine incorporation occurs principally into deoxyribonucleic acid during segmentation. After gastrulation, there is an incorporation of uridine into ribonucleic acid (both nuclear and cytoplasmic) as well.

BIOLOGY

Birefringence of Enamel Organic Matrix

To date little attention has been given to the appearances of the enamel organic matrix when examined between crossed nicols, and the few published observations show considerable disagreement. Cape and Kitchin[1], and Poole[2] reported that the enamel organic matrix is without intrinsic birefringence. Keil[3] and Schmidt[4] reported a weak positive intrinsic birefringence—the sign being described with respect to the long axis of the enamel prisms. Rushton[5] stated that this positive birefringence is strong, in fact stronger than the negative intrinsic birefringence of the mineral matter present in the mature tissue.

During current studies on the optical properties of dog enamel, results were obtained which support the views of Keil and Schmidt. In these studies ground sections, approximately 300µ in thickness, prepared from the developing maxillary permanent incisors of a two months old dog were demineralized in a formic and citric acid mixture. The demineralized sections were first imbibed for periods of 24 hr. in each fluid of a series prepared by mixing varying proportions of cedarwood oil ($n_D = 1{\cdot}505$) and monobromnaphthalene ($n_D = 1{\cdot}659$), and then examined between crossed nicols in monochromatic light—a sodium lamp being used as light source. The refractive indices of the imbibition fluids, determined with an Abbe refractometer, ranged from 1·505 to 1·598 by intervals of approximately 0·01. The retardation at selected points on the specimens was measured in each fluid by means of a Berek compensator.

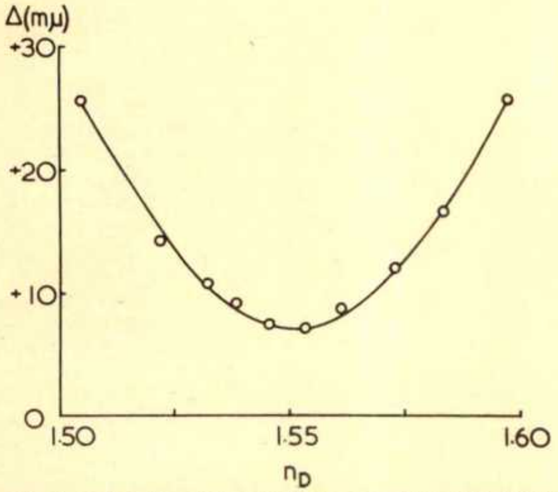

Fig. 1. Retardation of the enamel organic matrix as a function of the refractive index of the imbibition fluid

The type of imbibition curves thus obtained (Fig. 1) clearly indicates that in demineralized developing dog enamel organic matrix there is an interaction between positive form birefringence and positive intrinsic birefringence. Allowing for possible variations in prism direction giving rise to a crossed lamellar system[6], the strength of the positive intrinsic birefringence appears to be not less than 0·00002. Further, the refractive index of the organic matrix at this stage of development is shown by the imbibition curves to be about 1·55—a value confirmed by Becke line tests.

Thanks are due to Prof. L. R. Moore for making available the facilities to conduct this study in the Geology Department.

Placental Grafts in Rats

DURING studies of experimental infection of the rat placenta attempts were made to transplant placental tissue from the uterus to the mother's omentum. Grafts of the allanto-chorion were not successful; but the yolk sac membrane, when transplanted at 15 days pregnancy, grew in a most remarkable manner.

After a number of pilot experiments the following technique was adopted. The abdominal cavities of rats (Albino Wistar strain) at 15 days pregnancy were opened under open ether anæsthesia. The uterus with its contained conceptuses was removed, but the ovaries left intact. A portion of yolk sac was carefully dissected from a placenta and returned to the mother's peritoneal cavity where it was wrapped in the omentum. The abdominal wound was then closed.

Of 12 rats treated in this manner all except one showed evidence of transplant growth at autopsy 4, 8 or 12 weeks later. Seven transplants grew into large mucus-containing cysts, the largest being more than 2 in. in diameter (Fig. 1). On histological examination a variety of tissues were frequently found together in the same graft. These included epidermoid cysts containing keratin and hair, hair follicles, sebaceous and sweat glands, mucus-secreting epithelium, whorled masses of mesenchyme connective tissue, smooth and striated muscle, cartilage and bone. The mucus-secreting epithelium was usually organized with other tissues so as to resemble gut wall, in that there were villi and surrounding layers of smooth muscle (Fig. 2).

The possibility of dependence of these grafts on hormones has been briefly investigated; removal of the

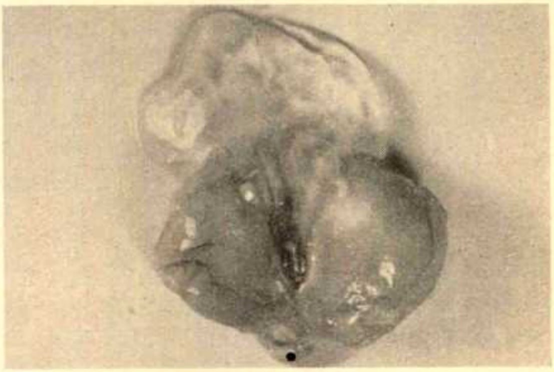

Fig. 1. Rat yolk sac graft to omentum, 12 weeks after transplantation. It has grown to more than 2 in. in diameter and contains large quantities of mucus

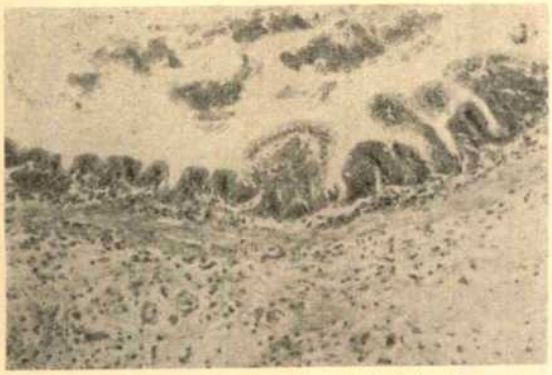

Fig. 2. As for Fig. 1. The wall of the graft is lined by mucus-secreting epithelium beneath which is connective tissue and layers of smooth muscle cells. Hæmatoxylin and eosin. (×150)

ovaries did not prevent successful transplantation, but the grafts did not grow to the same extent. Similar results occurred with homografts into 4 non-pregnant intact females. Homografts to 4 males grew in only 2 animals, where they produced just small quantities of mesenchyme connective tissue and tiny epidermoid cysts.

The variety of tissues produced in these grafts suggests that after transplantation to an unfamiliar site the endoderm and mesoderm cells of the rat yolk sac are capable of diverse differentiation.

As we have not found any previous account of similar transplants of placental tissue in rats we wish to place these initial results on record. Details and further experiments now in progress will be reported elsewhere.

In vitro Culture of *Musa balbisiana* Colla Embryos

THE culture of excised embryos has been reported for many plants[1], but, to our knowledge, there are no reports concerning the successful cultivation of embryos of seeded bananas. In the course of investigations on the rhizosphere of bananas, it became necessary to obtain plants of *Musa balbisiana* Colla, the roots of which were free of micro-organisms. The germination of intact seeds of this variety under sterile conditions was generally unsuccessful; hence, the possibility of obtaining sterile plants from excised embryos was investigated.

Preliminary studies were conducted with a modified Knudson's[2] medium, containing 2 per cent sucrose and 1·2 per cent agar. Intact seeds were surface sterilized in filtered $CaOCl_2$ (10 gm. $CaOCl_2$ in 150 ml. of distilled water)[2] *in vacuo* for 45 min. The embryos were removed aseptically and placed on 30 ml. of medium in 4 oz. wide-mouth screw-cap jars. Enlargement of the embryos was followed by leaf and root development. The roots, however, failed to penetrate the medium, and growth of the plantlets ceased after approximately 6 weeks, resulting ultimately in death of the plants. When young plantlets were transferred from the Knudson medium to that of Randolph and Cox[3], which contained only 0·7 per cent agar, root development improved and the roots penetrated into the medium.

In all current studies the Randolph and Cox medium is being used. The agar content of the medium has been further reduced to 0·5 per cent, since more rapid growth and healthier plants have been obtained with this concentration. Sucrose was found to be better than glucose or fructose as a carbohydrate source and 4 per cent was the optimum level. Intact seeds are surface sterilized by agitating for 30–35 min. in $CaOCl_2$ on a wrist-action shaker; the use of vacuum was found to be unnecessary in order to obtain sterility. The seeds are split longitudinally and the embryos aseptically removed. Excised embryos may be immersed in $CaOCl_2$ for up to 5 min. without deleterious effects, in agreement with Tukey's[4] experience with the embryos of stone fruits. In early experiments, the embryo, after enlargement, was re-oriented on the agar so that the cotyledon was placed in contact with the medium to provide a larger surface area for absorption. Repositioning was unnecessary when the low agar medium was used, since the weight of the embryo embedded the cotyledon into the soft agar.

Callus-like growth generally is evident 5–6 days after excision, followed by the appearance of the coleoptile and roots. Often, delicate hair-like growths arise from the surface of germinating embryos prior to the appearance of the coleoptile and roots. Two weeks after excision, the first leaf and roots have developed. A six-week old plantlet is illustrated in Fig. 1.

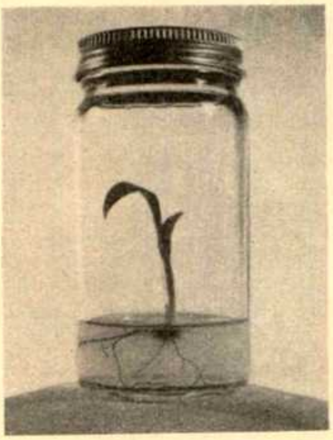

Fig. 1. *Musa balbisiana* Colla. Six-week-old plantlet developed in embryo culture

Plants developed from mature embryos, excised from seeds which were stored for periods of 3 weeks to 1½ years after harvest, were grown aseptically in the original culture vessels for 3 months. They were then transplanted to growth tubes wherein the roots have been maintained under sterile conditions for an additional 3 months. These plants are approximately 8 in. tall and have 8–10 fully developed leaves and well-developed root systems. The plants are smaller than seedlings of the same age which developed in soil under greenhouse conditions from intact seeds, but otherwise they appear to be similar in all respects.

The application of embryo culture to studies in plant breeding and nutrition have been pointed out by Crocker and Barton[1]. Our experiments have demonstrated that a wild relative of the commercial banana can be grown successfully from mature embryos and that the technique could possibly be applied to other varieties of bananas.

Studies are in progress on the nutrition, physiology, and morphology of *M. balbisiana* plants derived from embryos, results of which will be presented elsewhere.

SOIL SCIENCE

Weathering of Fly Ash

A CONSIDERABLE body of information is now available regarding the minerals present in fresh fly ash which are available to plants[1,2]. During combustion of the coal, adventitious clay minerals such as kaolinite are broken down, and a material is produced containing all the mineral constituents of coal, but with a very low cation exchange capacity (3 m.equiv. per 100 gm.). Many metal oxides are embedded in the glassy phase of the fly ash and may be released slowly over a period of time. In considering the possibilities of establishing crops or plant cover on fly ash deposits, it seemed worth while, therefore, to obtain information on the rate of change of selected constituents. Of particular interest were the elements, for example, boron and aluminium, that are present in quantities likely to be injurious to plants. In the studies to be briefly described here determinations were also made of phosphorus, potassium, calcium and iron in order to obtain any information regarding any likely change in fertilizer requirements as the age of the ash increases.

Ash tip areas covering an age-range of 0–25 years were available at Hams Hall power station and analyses have been made of samples collected from them. Phosphorus, iron and aluminium were determined in extracts obtained using Morgan's reagent. Boron, potassium and calcium were determined in water extracts using standard time procedure as for water-soluble soil constituents. These results, plotted against the age of the ash tip, are shown in Figs. 1 and 2 and indicate a rapid initial decrease in available concentration.

In order to see how far the changes could be due simply to leaching, columns 5 cm. in diameter and containing 25 gm. of fresh ash were set up and leached under a constant head of about 1–5 cm. of water and at a rate of about 1 ml./min. The leachate was collected in aliquots of 40 ml. for analysis. The curves obtained for potassium, calcium and boron (Fig. 3) are in agreement with field observations: a rapid initial decrease followed by a steady release of the elements. No phosphate, aluminium or iron was detected in the leachate. It was also noted that in the weathering of field samples the decrease in available iron was molecularly equivalent to the fall in available phosphate and that the fall in available calcium was similarly equivalent to the fall in available aluminium. These facts and the laboratory leaching curves suggest that, for these elements, the decrease in available concentration might be due to chemical fixation rather than to leaching out.

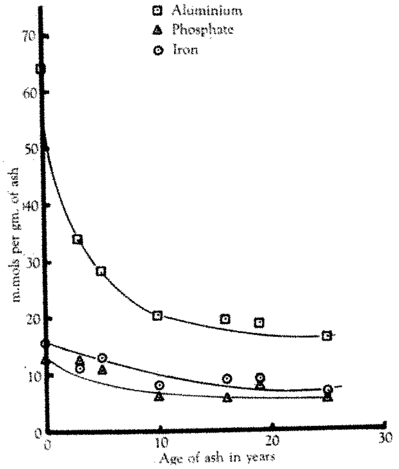

Fig. 1. **Amounts of aluminium, iron and phosphate in Morgan's extract of P.F. ash of varying age**

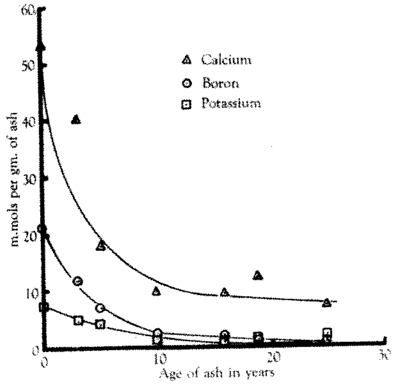

Fig. 2. **Amounts of calcium, boron and potassium in water extract of P.F. ash of varying age**

The equivalence of the change in available calcium and aluminium would suggest the formation of a dicalcium aluminate but there is as yet no evidence for this. X-ray studies[3] indicate the formation of a tetra calcium aluminate and some calcium sulphoaluminate after prolonged hydration and it seems likely that some interaction between calcium and aluminium takes place. The rapid loss of soluble calcium found in the leaching experiments would not be likely to occur to the same extent under field conditions as the relatively soluble calcium hydroxide would be rapidly carbonated and fixed in an insoluble form.

The fall in available concentration of elements injurious to plant growth on the fly ash, namely boron and aluminium, is also of particular interest. It may be seen from Figs. 1 and 2 that these elements fall rapidly from a high injurious level to a level approaching that of a normal soil (for example, 1 p.p.m. water-soluble boron[4]). Fig. 4 shows how the boron content of wild white clover grown on ash falls with increasing age of the ash used. It may be concluded that although the range of possible crops

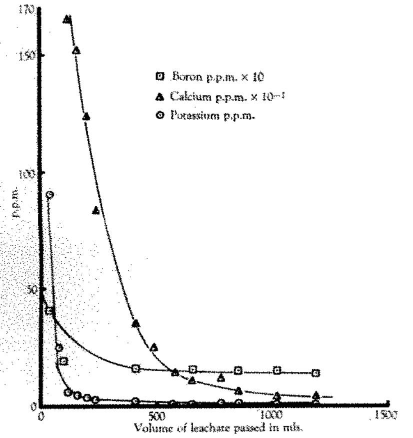

Fig. 3. Laboratory leaching curves

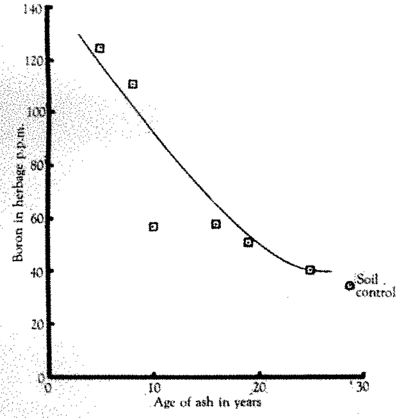

Fig. 4. Boron in plant tissue grown upon ash of varying age

is limited during the first few years of the life of a fly ash tip a considerably wider range of crops may be used as the ash weathers.

In using already existing ash tips of different ages for the investigation of weathering it has been assumed that (*a*) the coal source and composition had remained reasonably constant over the 25-year period and (*b*) that improved methods of coal grinding, resulting in the production of a finer ash, have not significantly altered the availability of elements as for example by increasing surface area. The latter possibility cannot be ignored but the agreement between the column leaching experiments and the field observations indicates that a true picture of weathering under field conditions has been obtained. The samples examined were procured from areas with free drainage and no evidence of waterlogging. The rate of decrease in soluble constituents in areas with a high water table and/or impeded drainage may well be considerably lower.

PATHOLOGY

Periosteal Osteoclasts, Skeletal Development and Ageing

As far back as 1873, Kölliker[1] observed the existence of osteoclasts in the periosteum of normal bone. Lacroix[2] also made several references to the presence of periosteal osteoclasts during development of the perichondral collar of long bones. Quantitative information, however, is not available concerning the size of the population of periosteal osteoclasts and the appearance, disappearance, and stability of the population during ageing. The importance of the presence of these cells at periosteal sites has been largely neglected. Environmental conditions which are found in the periosteum make for an excellent study of osteoclastic origin, function, fate and biochemical nature.

Jackson[3] and Jordan[4] have reported mitosis in the nuclei of osteoclasts. Amitosis has also been noted by Kolliker[5]; however, these events are extremely rare, and cannot account for the rapid appearance and disappearance of large numbers of osteoclasts. Kölliker maintained that osteoclasts originated from the fusion of osteoblasts. More recently Heller *et al.*[6] described the formation of osteoclasts from osteoblasts or osteocytes under the influence of toxic doses of parathormone.

Because of the nature of the periosteum, it was felt that a study of periosteal osteoclasts may reveal information concerning the origin and fate of osteoclasts under normal conditions, which could not be readily observed in the more complex environment of the metaphysis. For a better comprehension of bone development and ageing, population studies were made from the left femora of 45 female mice of the Brookhaven National Laboratory strain of Swiss Albino. The right femur of each mouse was fractured by digital pressure applied to the mid-shaft under ether anæsthesia. The femora were fractured at 1, 5, 8, 26, and 52 weeks of age, and the mice were killed 24 hr., 1 week, and 2 weeks post-fracture. One hour before they were killed, they received a subcutaneous injection of tritium-labelled thymidine in sterile aqueous solution (0·5 μc./gm. body-weight). Stripping film autoradiographs were prepared from paraffin sections of whole decalcified femora. Additional sections were stained routinely with hæmatoxylin and eosin.

The tritium-labelled thymidine technique and interpretation of data are based on the successful studies employed by Hughes *et al.*[7], Cronkite *et al.*[8,9], Bond *et al.*[10], and Quastler and Sherman[11].

The total population of periosteal osteoclasts was found to be much larger in animals the femora of which were undergoing active bone development and remodelling than in older mice. Counts made of the population of periosteal osteoclasts of young mice revealed extensive fluctuations within very short periods of time (Table 1 and Fig. 1). A more stable population was exhibited by older animals, the total osteoclastic population of which was much lower than the younger mice. Considerable differences were found between counts made from the anterior and posterior aspects of the femur. A shift in the position of the major population of osteoclasts was observed at least 3 times during the ages studied. This shift is indicated in Fig. 1 at the points of intersection.

It is interesting to point out that on numerous occasions in animals of different ages cells were

Table 1. AVERAGE NUMBER OF OSTEOCLASTS PER UNIT DISTANCE* OF PERIOSTEUM COVERED AT THE DISTAL EPIPHYSEAL ASPECT OF MOUSE FEMUR

* An average of 173 unit distances covered per age group.

observed having a size comparable to osteoblasts. Except for the presence of a single nucleus, the cells answered to the description of osteoclasts in all cytological respects. The mononucleated state was verified from serial sections. These mononucleated cells, which in many instances resided in well-formed Howship's lacunæ, exhibited an eosinophilic, foamy cytoplasm, lacking in the presence of a juxtanuclear vacuole. A juxtanuclear vacuole is seen in active osteoblasts. Cells of this description were never encountered in the metaphyses. Ch'uan[12] has observed mononucleated osteoclasts in the jaws of a two-day-old hamster and the stripped periosteum of a newly born goat.

Several foci of osteoblasts arranged in tight clusters were observed at ages where active periosteal osteoclast formation was taking place. Individual cells making up these clusters finally lost the identity of their cytoplasmic borders, cytoplasmic basophilia, and juxtanuclear vacuoles. The usual population of periosteal osteoblasts was reduced in the immediate areas where osteoclasts were being formed.

Autoradiographs of intact femora revealed an essentially weakly labelled periosteum. The highest labelling occurred at the perichondral region. Osteogenic cells of the osteogenic layer of the periosteum near the fibrogenic layer were labelled most frequently. Osteoblasts, however, were rarely seen labelled. Osteoclasts, on the other hand, were never seen labelled above background (Fig. 2). This is also true of metaphyseal osteoclasts. With increasing age labelling of periosteal cells became more infrequent.

Within 24 hr. after fracture and at all ages studied, the periosteum became increasingly labelled about the fracture site. In older animals, however, the overall labelling was not as high as the level found in younger mice. Periosteal labelling continued to increase until the osteogenic cells of the fracture callus differentiated into cartilage cells (Fig. 3). Diminished periosteal labelling was noted when the active replacement of the cartilagenous callus by endochondral ossification took place. With increasing age there was a retardation of fracture healing in mice. Reduction in the rate of bone repair has been observed and reported for rat femora[13,14]. The degree of labelling was dependent upon the stage of repair that the fracture was in, and the age of the animal.

No uptake of tritium-labelled thymidine was observed in the numerous osteoclasts which appeared during fracture healing. Labelling of osteocytes was never seen.

The results showed that during the remodelling of the ends of the femur, the population of osteoclasts present in the periosteum fluctuated radically within short periods of time. Since active formation of periosteal osteoclasts was observed from the fusion of osteoblasts, and degenerating osteoclasts were

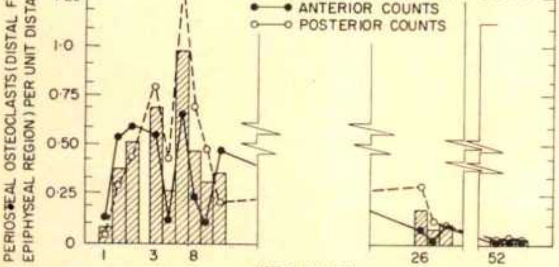

Fig. 1. Graph showing a comparison between the size of the osteoclastic population of the anterior and posterior aspects of the periosteum in the distal end of the femur at different ages

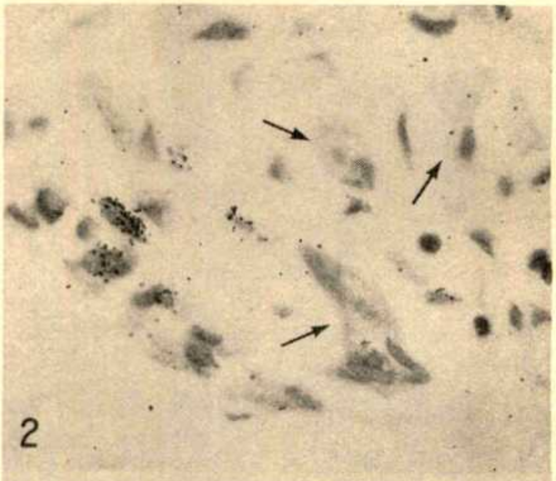

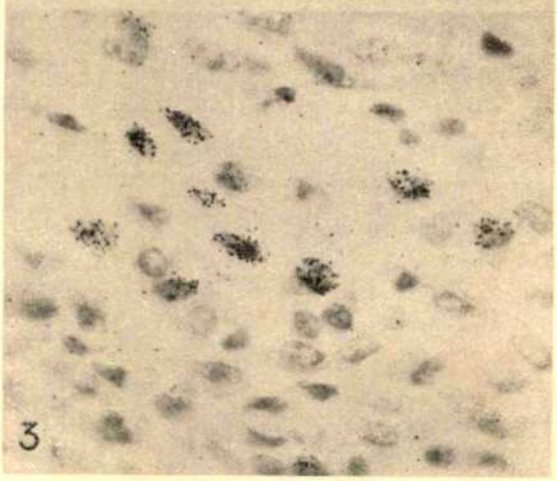

Fig. 2. Photomicrograph revealing tritium-labelled thymidine marking of osteoblasts during active fracture healing in a 2-week-old-mouse the femur of which had been fractured 1 week prior. Arrows point to non-labelled osteoclasts (× c. 534 oil)

Fig. 3. Photomicrograph revealing tritium-labelled thymidine marking of osteogenic cells of the periosteum active in the production of the fracture callus. The cells are undergoing transformation into chondrogenic cells in a 2-week-old mouse the femur of which had been fractured 1 week prior (× c. 560 oil)

not readily found, a reduction in population within one week's time is believed to have occurred as a result of the dissociation of osteoclasts into precursor cells. It is possible that the population of osteoclasts migrated from one position to another. Had this migration taken place, there would have been fewer periosteal cells present in such regions, unless the other periosteal cells filled the gap. No deficiency was encountered in the population of periosteal osteoblasts or osteogenic cells at that time. At a point, however, when the total (anterior and posterior) population of osteoclasts diminished rapidly, the presence of degenerating cells should have been seen. Nevertheless, degenerating osteoclasts were not encountered. Autoradiographic results indicated that there was no uptake of tritium-labelled thymidine by periosteal osteoclasts and hence there occurred neither deoxyribonucleic acid synthesis nor reproduction by mitotic division.

The observations indicate that periosteal osteoclasts derive their origin from osteoblasts and their fate is to dissociate into precursor cells. It appears that with increasing age beyond the period of active bone remodelling, there is a decrease in the population of osteoclasts; however, changes in age in individual osteoclasts were not seen.

I wish to acknowledge the suggestions of Dr. E. P. Cronkite, and the technical assistance of Miss M. Pavelec.

ARCHÆOLOGY

An Alternative Interpretation of the Supposed Giant Deciduous Hominid Tooth from Olduvai

DR. L. S. B. LEAKEY has reported[1,2] the discovery at Olduvai of what he regards as a large second lower deciduous molar of a hominid exhibiting affinities with *Sinanthropus* and the Heidelberg jaw, but not with australopithecines. Associated with it was a worn deciduous canine. The purpose of this communication is to show that the molar is, in fact, a permanent upper tooth, probably of an australopithecine.

The molar appears to be a somewhat aberrant specimen, since the morphologically less-stable areas —anterior and posterior foveæ and either the lingual or buccal faces, depending on whether the tooth is maxillary or mandibular—have many accessory cusps.

Assuming the tooth to be mandibular, as Leakey does, and ignoring the accessory cusps for the present, it is not possible to fit the main cusp or fissure patterns into either of the two common types for hominoid mandibular molars: the five- or four-cusped types. The relationship of the cusps to each other is wrong: the buccal cusps are too far back relative to the lingual ones. Furthermore—a major difficulty in interpreting the tooth as mandibular—the anterior buccal cusp ('protoconid') and the distal lingual cusp ('entoconid') are linked by an almost cusp-high crest. This divides the fissure system into two quite separate parts, while even in very worn mandibular molars of earlier hominids the fissure system separates these two cusps deeply and is not divided into two portions. Also, this oblique, high crest with a deep fissure posterior to it cutting deeply between the 'protoconid' and 'hypoconid', distinctly sets off an almost symmetrical anterior triangle of major cusps from a single, semi-isolated major cusp posteriorly. This is a feature not found on mandibular molars.

On the other hand, the high, oblique crest in this position on the crown, the anterior trigon of three major cusps and a postero-medial semi-isolated cusp (hypocone) are not merely common on maxillary molars but also are regarded as being the standard pattern for them. Leakey regards two large accessory cusps in the posterior fovea as very unlikely on a maxillary tooth. Fig. 1 (*C*) illustrates an almost identical condition in an upper molar; one *Australopithecus* upper molar from Sterkfontein has no less than five accessory cusps in this position.

The crown morphology is thus clearly in favour of this tooth being maxillary. The disposition of the roots provides an absolute check, since early hominid deciduous or permanent mandibular molars have two roots, an anterior and a posterior, while maxillary ones have a single lingual and two buccal roots. There can thus be no confusion. Although damaged, the Olduvai specimen clearly has two buccal roots and a larger, single lingual one. For comparison a maxillary permanent australopithecine molar in a similar state of preservation is shown in Fig. 1 (*D*) along with the entirely different condition in an australopithecine deciduous lower second molar (Fig. 1, *F*). The roots of the Olduvai specimen manifestly could not belong to a mandibular tooth.

Leakey regards the tooth as deciduous because of: (i) divergent roots, (ii) constriction of the neck, (iii) nature of the roots, and (iv) association with a lower deciduous canine.

Divergent roots and a constricted neck, in earlier hominid molars, do not necessarily indicate deciduous teeth, since the permanent teeth commonly have both features well developed. This is well shown by the extensive collections of australopithecine teeth now known. As already indicated in the case of (iii), the nature of the roots is more consistent with the specimen being a permanent upper tooth. Finally, (iv) is a broken reed. If this tooth is regarded as a second lower deciduous molar, then it is highly

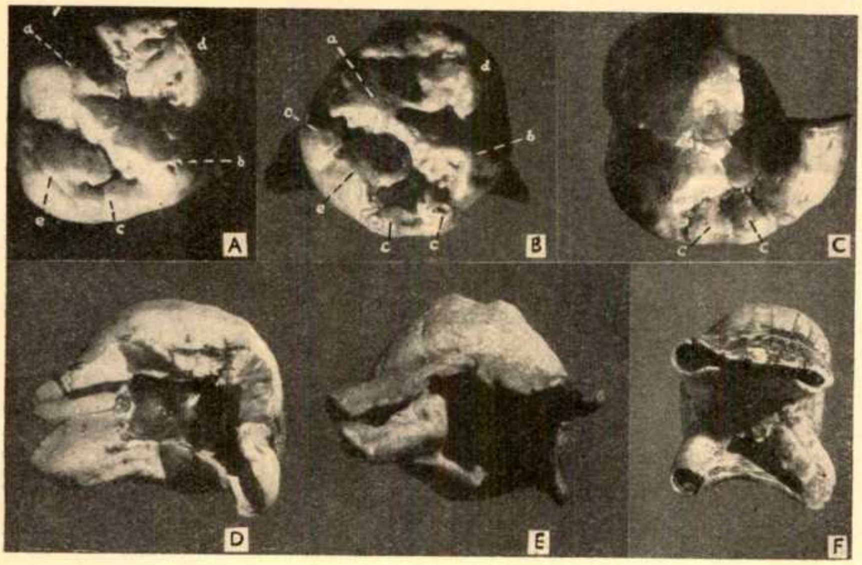

Fig. 1. (*A*) and (*C*) Occlusal views of australopithecine maxillary molars. (*B*) Occlusal view of Olduvai molar. View of the root system (damaged) of an australopithecine maxillary molar (*D*) and of the Olduvai molar (*E*). (*F*) View of root system of an australopithecine deciduous mandibular molar. In all cases the lingual side is to the left. In the upper row the anterior end is at the top and in the lower row at the bottom. In (*A*) and (*B*) the high oblique crest links *a* and *b*; the trigon is formed by *a*, *b* and *d*. *a*, Protocone; *b*, metacone; *c*, accessory cusps; *d*, paracone; *e*, hypocone

unlikely that it belonged to the same individual as the deciduous canine. The latter is well worn, and had already lost about half the crown height. At this stage, dm_2 of the individual would already have been appreciably worn, not virtually unworn as is the Olduvai molar. Furthermore, at that stage permanent molars with fully formed crowns would also have been present. On the other hand, while the deciduous canine is only very slightly larger than the observed range of the very small collection of australopithecine equivalents, the molar is appreciably larger than the largest australopithecine dm_2 known, but is well within the observed range for permanent molars.

I believe, therefore, that the Olduvai molar is neither deciduous nor mandibular, but is a permanent upper tooth, probably australopithecine.

J. T. ROBINSON

Transvaal Museum,
Pretoria.

[1] Leakey, L. S. B., *Nature*, **181**, 1099 (1958).

[2] Leakey, L. S. B., *Illus. Lond. News*, **232**, 1104 (1958).

IN my original paper I was at pains to point out that of a number of dental surgeons and anatomists to whom I had then showed this tooth, no two were agreed upon what its place was in the dental series. Since that time I have had many other views put to me in letters and also verbally. Clearly, the tooth is so aberrant there is little hope of agreement.

It seems to me to be immaterial, at the moment, as to which opinion is correct. What is certain and important is that it is: (*a*) a very large *hominid* molar; (*b*) that it was found within a few inches of a small deciduous canine tooth and within a few minutes; (*c*) that it comes from the base of Bed II, Olduvai, associated with Stage I of the Chellean culture, and was found on a living floor; (*d*) that the relative size of the molar to the canine is comparable to that seen in *Zinjanthropus*, and to a lesser extent in *Paranthropus* and *Australopithecus*.

I still retain my opinion that, in spite of its unusual form, it is a lower deciduous molar, and the fact that I have now three modern hominid lower deciduous molars (taken from mandibles) that similarly have three roots and not two, and set in just this manner, shows that Robinson's reliance on the number of roots, to clinch his argument, is not realistic. Similarly, while I agree (and also stressed in my original paper) that if the tooth is, as I believe, a lower molar, it does *not* show either of the two common types of cusp patterns, the cusp pattern which it does exhibit is, nevertheless, one which does occur in Hominids, both recent and extinct, as I showed before.

Since that article was written, I have found that the same pattern occurs in many other modern mandibular molars, and we must indeed now regard it as a third fairly common pattern, since I found it in 15 per cent of a random sample of mandibles.

Among the many anatomists who have now seen the fossil tooth in question, there are some who agree wholly with me; there are others who agree with Robinson, and there are yet others whose views do not agree with either of us. Everything depends upon what weight one gives to the number and disposition of the roots, as compared with the disposition of the cusps and their interpretation.

It appears that Robinson, from his study of the cast, is clearly not aware that what he refers to as "the ridge" linking the two cusps is divided by a very clear fissure, and is not a continuous ridge at all. This fissure shows very clearly in the photograph which I published and which was taken of the original tooth, but does not show in the photograph used by Robinson, which is apparently taken of a cast.

Finally, let me say that since the molar teeth of *Zinjanthropus* exceed the molar teeth of *Australopithecus* or *Paranthropus* in size, it is not unlikely that the deciduous molars of a descendant of *Zinjanthropus* should also be much larger than the deciduous molars of the known South African Australopithecinae, and since Chellean Stage I is a direct derivative of the Oldowan culture, it is reasonable to expect that the makers of Chellean Stage I will prove to be more advanced descendants of *Zinjanthropus*; heading in the *Homo* direction.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, February 8

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. L. Goodstein : "The Significance of Incompleteness Theorems".

Institution of Electrical Engineers, Electronics and Communications Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Present Views on Ground-Wave Propagation" opened by Mr. G. Millington.

University of London (at Senate House, London, W.C.1), at 5.30 p.m.—Prof. A. T. Ippen (Massachusetts Institute of Technology) : "Tide-dynamics in Estuaries".* (Further lectures on February 10 and 12.)

Royal Institute of Chemistry (joint meeting with the Sir John Cass College Chemical Society, at the Sir John Cass College, Jewry Street, London, E.C.3), at 6.30 p.m.—Prof. E. D. Hughes, F.R.S. : "Reaction Mechanisms".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. H. J. B. Harding : "The Channel Tunnel".

Tuesday, February 9

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Textile Institute (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Mr. E. Roberts and Mr. F. P. Thompson : "Domestic Washing of Textiles".

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. E. C. Carter : "Model Testing in the Aircraft Research Association".

Radar and Electronics Association (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7.30 p.m.—Mr. E. Wolfendale : "Transistors—To-day and To-morrow".*

Wednesday, February 10

Physical Society, Low Temperature Group (at the Royal School of Mines, Prince Consort Road, London, S.W.7), at 4 p.m.—Dr. H. M. Rosenberg : "Some Low Temperature Experiments on the Alkali Metals".

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Sir Edward Bailey and Dr. W. J. McCallien : "Some Aspects of the Steinmann Trinity—Mainly Chemical" ; Dr. M. J. Fleuty : "The Three-Fold Systems in the Metamorphic Rocks of Upper Glen Orrin, Ross-shire and Inverness-shire" (to be read by Prof. J. Sutton).

Institution of Electrical Engineers, Supply Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. R. L. Grimsdale and Mr. P. H. Sinclare : "The Design of Housing-Estate Distribution Systems using a Digital Computer" ; Mr. U. G. W. Knight : "The Logical Design of Electrical Networks using Linear Programming Methods".

Society of Chemical Industry, Food Group—Nutrition Panel (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mrs. P. Fisher and Miss M. Corbridge : "The Public Attitude to Nutrition".

Institute of Metals (at 17 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. W. C. Winegard (University of Toronto) : "Solidification of Alloys".

Institute of Wood Science (at Imperial College, Exhibition Road, London, S.W.7), at 6.45 p.m.—Mr. G. Garlick : "The Quality and rading of Softwood in Relation to End Use".

British Interplanetary Society (in the Hoare Memorial Hall, ch House, Great Smith Street, Westminster, London, S.W.1), .m.—Prof. Alla Masevich : "Soviet Space Research".

ty for Psychical Research (at Kensington Town Hall, n High Street, London, W.8), at 7 p.m.—Mr. G. Zorab : hips in Spontaneous Paranormal Phenomena".

Engineering Society, London Branch (at Hope House, ter Street, Westminster, London, S.W.1), at 7 p.m.—Ball : "Uses of New Metals".

of Clinical Biochemists, Southern Region (in Lecture Theatre of the new Middlesex Hospital Medical , Cleveland Street, London, W.1), at 7.30 p.m.—Dr. : "Pitfalls in the Investigation of Metabolism through Some Cautionary Examples from Recent Studies of , Schizophrenia and Hartnup Disease".

Thursday, February 11

y (at Burlington House, Piccadilly, London, W.1), iss Elsie M. Widdowson and Prof. R. A. McCance, ffects of Accelerating Growth. I : General Somatic Mr. J. W. T. Dickerson and Miss Elsie M. Widdowects of Accelerating Growth. II : Skeletal Develop- Hicken and Mr. P. L. Krohn : "The Histocompatnts of Ovarian Grafts in Mice".

ty of London (at Burlington House, Piccadilly, 5 p.m.—Prof. C. F. A. Pantin, F.R.S. : "Alfred nd his Pre-Darwinian Essay" ; Mr. Quentin Bone : the Chordates", with a Discussion to be opened by r.

Antiquarian Horological Society (at the Science Museum, South Kensington, London, S.W.7), at 7 p.m.—Mr. B. Caillard : "Pendulum Watches".

Society of Instrument Technology (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. T. A. Lucas : "Measurement, Automatic Control and Data Reduction as Applied to a Cyclic Plant".

Chemical Society (in the Lecture Theatre, The Royal Institution, Albemarle Street, London, W.1), at 7.30 p.m.—Prof. P. L. Pauson : "Hydrocarbon-metal Carbonyls" (Tilden Lecture).

Friday, February 12

Association of Applied Biologists (at the Royal Entomological Society, 41 Queen's Gate, London, S.W.7), at 10.50 a.m.—Meeting on "Aspects of Crop Physiology".

British Psychological Society, Occupational Psychology Section (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p.m.—Annual Meeting. Mr. D. E. Broadbent : "Industrial Inspection and Recent Advances in Psycho-Physics" (Chairman's Address).

University of London (at Bedford College, Regent's Park, London, N.W.1), at 5.30 p.m.—Prof. E. Wegmann (Neuchâtel) : "Some Aspects of the Geology of the Basements".*

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. N. D. Norman and Mr. T. Clutterbuck : "Choice of Aerial Vehicle".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Mr. F. T. Bacon : "Fuel Cells : Will They Soon Become Major Sources of Electrical Energy ?"

Saturday, February 13

Biochemical Society (at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 10 a.m.—Symposium on "The Biochemistry of Mucopolysaccharides".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned :

Assistant (honours agricultural science graduate) in Crop Husbandry—The Secretary, Faculty of Agriculture, University College, Glasnevin, Dublin (February 12).

Lecturer in the Department of Mathematics—The Secretary, The University, Edinburgh (February 13).

Senior Lecturer or Lecturer in the Department of Electrical Engineering (Electronics)—The Registrar, The University, Liverpool, quoting Ref. CV/N (February 13).

Lecturer or Senior Lecturer in Biology ; and a Lecturer in Chemistry in the Training Department—The Warden, University of London Goldsmiths College, London, S.E.14 (February 15).

Plant Cytogeneticist, Scientific Officer (with an honours degree in botany, and preferably postgraduate experience in cytological research) at the Royal Botanic Garden, Edinburgh, for the cytological exploration of the living collections in the Garden and the development of the cytogenetic contribution to problems of plant taxonomy—The Establishment Officer (B), Ministry of Works, 122 George Street, Edinburgh 2 (February 15).

Senior Research Assistant (with a Ph.D. in theoretical physics or equivalent research qualifications, and preferably some experience in many body problems, or the methods of field theory) to Dr. N. H. March in the Department of Physics, for work concerned with electron correlation in metals—The Registrar, The University, Sheffield 10 (February 15).

Assistant Experimental Officer or Experimental Officer (graduate) in the Plant Pathology Department, for work on insect transmission of viruses—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (February 20).

Assistant in Bacteriology (Science)—The Secretary of University Court, The University, Glasgow (February 20).

Demonstrator in Geography at the University of New England, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (February 20).

Lecturer and an Assistant Lecturer in Zoology—The Registrar, The University, Nottingham (February 20).

Lecturer in Philosophy ; a Lecturer in Social Anthropology ; and an Assistant Lecturer in Geography—The Secretary, The Queen's University, Belfast (February 20).

Lecturer or Assistant Lecturer in the Department of Applied Mathematics—The Registrar, The University, Liverpool (February 22).

Lecturer (preferably with an interest in biophysics) in Physics—The Secretary, St. Mary's Hospital Medical School (University of London), Paddington, London, W.2 (February 22).

Assistant Lecturer in Mathematics (Pure or Applied)—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (February 25).

Principal Lecturer and a Senior Lecturer in the Department of Mechanical Engineering ; Senior Lecturers (3) in the Department of Electrical Engineering ; a Lecturer and an Assistant Lecturer in the Department of Applied Physics ; a Senior Lecturer in Metallurgy and a Lecturer in Inorganic Chemistry in the Department of Chemistry, Metallurgy and Textiles—The Registrar, Lanchester College of Technology, Butts, Coventry (February 25).

Lecturer (with a good honours degree in electrical engineering or physics, and suitable experience in light-current electrical engineering and applied electronics) in Electrical Engineering—Joint Clerk to the University Court, Queen's College (University of St. Andrews), Dundee (February 27).

CHAIR AND HEADSHIP OF THE DEPARTMENT OF ZOOLOGY, and CHAIR AND HEADSHIP OF THE DEPARTMENT OF MINING—The Registrar, The University, Leeds 2 (February 29).

LECTURER or ASSISTANT LECTURER IN BIOCHEMISTRY—The Registrar, The University, Leeds (February 29).

LECTURER (with experience in archæological field work, and qualified particularly in British archæology) IN ARCHÆOLOGY—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (February 29).

SCIENTIFIC OFFICERS/SENIOR SCIENTIFIC OFFICERS (analytical or inorganic chemists with a first- or second-class honours degree in chemistry or equivalent) IN THE LABORATORY OF THE GOVERNMENT CHEMIST, D.S.I.R., London, for analytical work including research into the development of advanced methods of analysis—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting Ref. 487/9A (February 29).

RESEARCH ASSISTANTS (2) (with a first- or second-class honours degree in chemistry or Graduate Member of the Royal Institute of Chemistry) IN CHEMISTRY—The Registrar, Lanchester College of Technology, Butts, Coventry (March 1).

RESEARCH FELLOW IN CRYSTALLOGRAPHY (COMPUTING) in the School of Chemistry, to take charge of the coding and supervise the use of computer programmes for crystallographic calculations of the high-speed 'Silliac' computer—The Registrar, University of Sydney, Sydney, N.S.W., Australia (March 4).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOW IN CHEMISTRY OR PHYSICS—The Registrar, The University, Leicester (March 5).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN BIOCHEMISTRY, CHEMISTRY, ENGINEERING AND PHYSICS—The Secretary and Registrar, The University, Southampton (March 5).

LECTURER IN APPLIED MATHEMATICS—The Registrar, King's College (University of Durham), Newcastle-upon-Tyne (March 5).

ASSISTANT LECTURER (veterinary surgeon, or with a degree in physiology) IN THE DEPARTMENT OF PHYSIOLOGY—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (March 15).

LECTURER or ASSISTANT LECTURER IN BOTANY at the University of Malaya (Singapore Division)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 15).

CHAIR OF ZOOLOGY in the Imperial College of Tropical Agriculture, Trinidad, West Indies—The Secretary, Imperial College of Tropical Agriculture, 40 Norfolk Street, Strand, London, W.C.2 (March 17).

LECTURER (qualified in either pure or applied mathematics) IN MATHEMATICS—The Secretary of University Court, The University, Glasgow (March 19).

ASSISTANT LECTURER or LECTURER (with a strong interest in some branch of theoretical physics, or in information theory, or some other branch of applied mathematics) IN APPLIED MATHEMATICS—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (March 21).

LECTURER or ASSISTANT LECTURER IN ZOOLOGY at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong and London, March 21).

LECTURERS IN PURE MATHEMATICS—The Secretary, The Queen's University, Belfast (March 21).

LECTURER (preferably with interests in theoretical electromagnetics and/or plasma theory) IN PHYSICS—The Secretary, The Queen's University, Belfast (March 30).

CHAIR OF BOTANY in the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong and London, March 31).

ASSISTANT LECTURER (Grade "B") TO TEACH ORGANIC AND GENERAL CHEMISTRY—The Clerk to the Governors, Northern Polytechnic, Holloway, London, N.7.

ASSISTANT LECTURER IN BOTANY; an ASSISTANT LECTURER IN CHEMISTRY; an ASSISTANT LECTURER IN PHYSICS; an ASSISTANT LECTURER IN PHYSIOLOGY; and a RESEARCH ASSISTANT (qualified in biochemistry, physiology or zoology) TO THE PROFESSOR OF ZOOLOGY—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

ELECTRONICS ENGINEER (Experimental Officer grade), to collaborate with research and instrument development in marine physics at Millport—The Secretary, Scottish Marine Biological Association, Millport, Isle of Cumbrae, Scotland.

EXPERIMENTAL OFFICER (preferably with a pass degree or H.N.C., and experience in electronic and optical recording techniques, or G.C.E. in five subjects, including two scientific or mathematical subjects at "A" level), to work in collaboration with scientists on shock and detonation wave phenomena using high speed electronic and optical equipment—The Senior Recruitment Officer, The Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. A.2366/34.

LECTURER IN MATHEMATICS; and a LECTURER IN STATISTICS AND MATHEMATICS—The Registrar, Bradford Institute of Technology, Bradford 7.

MASTER TO TEACH PHYSICS to Open Scholarship level—The Headmaster, Latymer Upper School, Hammersmith, London, W.6.

MASTER TO TEACH PHYSICS to Sixth Form standard—The Headmaster, Merchant Taylors' School, Sandy Lodge, Northwood, Middlesex.

SENIOR LECTURER (with a good honours or higher degree, with teaching and preferably appropriate industrial experience) IN THE DEPARTMENT OF CHEMISTRY AND METALLURGY, to teach inorganic chemistry to final B.Sc. and Part II Grad.R.I.C. level—The Principal, Rutherford College of Technology, Northumberland Road, Newcastle-upon-Tyne.

SENIOR TECHNICIAN IN THE BIOCHEMISTRY DEPARTMENT—The Secretary, Queen Mary's Hospital for the East End, Stratford, London, E.15.

SENIOR TECHNICIAN (preferably man 25–30 years of age, with biochemical and practical laboratory experience) for newly formed Research Department of Immunology—The Secretary, Wright-Fleming Institute, St. Mary's Hospital Medical School, Paddington, London, W.2.

EVOLUTION OF MANKIND

IN his speech opening the debate on science in civil life in the House of Lords on December 9, Lord Taylor, in referring to the vanishing difference between pure and applied science, quoted both from Lord Adrian's recent Fawley Lecture on November 17 to the University of Southampton on "The Risks of Progress" and from Prof. P. B. Medawar's Reith Lecture on "The Future of Man". Lord Adrian remarked that we have become more and more aware that concentration on practical issues may lead to big theoretical advances ; and he added that there is no longer any stigma attached to an idea or technique derived from a workshop rather than a university. Lord Taylor observed that applied science might lead to unexpected fundamental discovery, and pure science might yield utilitarian results when least intended ; nevertheless, the difference remains, and in applied science someone must indicate the objective.

Considering more particularly medical science, Lord Taylor referred to the growing importance of producing health and fitness, but he used the term fitness in a rather wider sense than that of 'net reproductive advantage' used by Prof. Medawar in his second Reith Lecture, though Lord Taylor did not deny the importance of this definition in long-term genetic study. In this second lecture, Prof. Medawar considered the question whether man could go on evolving in the future as he has evolved in the past, or whether there is a good reason why his evolution should now have come to an end, and then asked, as a subsidiary question, whether there is any real reason for supposing that advances in medicine and hygiene are undermining the fitness of the human race. It is in this context that Prof. Medawar uses the word 'fitness' in the sense of 'net reproductive advantage', as it is generally used by students of heredity, though he recognizes that it neglects much that is deeply important in human life.

It may be recalled that in his first lecture, Prof. Medawar had emphasized the fallibility and limitations of our efforts to predict the future. Nevertheless, he maintained in his second lecture that it is not true to say that advances in medicine and hygiene must cause a genetical deterioration of mankind ; there is more to be feared from a slow decline of human intelligence. But if that is happening, it is because the rather stupid are biologically fitter than those who are innately more intelligent, not because medicine is striving to raise the biological fitness of those people who might otherwise be hopelessly unfit.

This relation between intelligence and fertility was discussed more particularly in his fifth lecture, in which Prof. Medawar pointed out that while the average level of intelligence may in fact decline, this is no more than a presumption, first because one highly important piece of information, about the intelligence of married couples who have no children, or of people who never marry at all, is missing, and secondly, because we do not yet know exactly how differences of intelligence are inherited. Moreover, profound changes in fertility have been taking place during the past fifty or a hundred years, and they are not yet complete. Any decline of intelligence may be a purely temporary phenomenon, marking the transition from free reproduction accompanied by high mortality to restricted reproduction accompanied by low mortality.

There may thus be less difference between Prof. Medawar's views and that expressed by Lord Adrian in his Fawley Lecture than appears at first sight, when we contrast Prof. Medawar's words with Lord Adrian's balance sheet. Lord Adrian, too, emphasizes the need for much more information, and he himself suggests that we need not be too downcast at the picture he presented of the result of indiscriminate life-saving. We have succeeded so well, he observes, in our aim at keeping alive every child that is born that we are certainly preserving many unfavourable genes which would otherwise have died out. "If we set out to save the unfit we must expect more unfitness in the world and more inheritance of the factors which promote it. Even if the radiation level remains as it now is, the advance of science can harm the genetic constitution of the race".

Lord Adrian goes on to point out that even a doubling of the mutation-rate, however, would not double the load of inherited weakness until many generations had elapsed, for many of the faulty genes will be recessive or sex-linked. In the next thirty years we can confidently expect a great increase in our understanding of the ultimate structure of living matter, of viruses and chromosomes and of the whole molecular mechanism of inheritance and growth. While it would be idle to look further ahead than one generation, Lord Adrian is confident that at the present rate of progress the medical science of our great-grandchildren will make them far more capable of preserving the race. Moreover, Prof. K. Mather, in a recent broadcast on heredity and environment, has stressed the way in which human ideas and the power to record and communicate them make our social evolution a far more rapid process than our biological evolution. The effects of new knowledge take far less time to be established than those of a new mutation, and while the prospect of decline in the level of human ability is far more disturbing than that of a rise, Lord Adrian believes that our increased knowledge will enable us to find a way to escape the genetic dangers which may threaten us before our stock has been seriously harmed.

That, however, does not give a fair picture of Lord Adrian's approach to this question of the risks of progress. He began by directing attention to the way in which academic science and its relation to technology and industry have been violently forced out of the pattern which T. H. Huxley prescribed for it in the Victorian period. We have become painfully aware of the risks we may be running in allowing free play to all the developments of science in the technological field, and while most of us would be shocked at the suggestion of banning any attempt to pursue a line of scientific inquiry which aimed primarily at increasing our understanding of the natural world, most of us would cheerfully agree to the prohibition of work on certain practical developments if we thought they might have a harmful effect on the human race.

It is at this point that Lord Adrian brought this distinction between pure and applied science sharply into focus on the problems of the under-developed territories of the world. Much remains to be done before those territories can be freed from poverty and hard labour; but the objective cannot be attained if the timing is not adequately supervised, if the population of the world is allowed to increase more rapidly than we can increase our means for feeding and housing it, if we exhaust our stores of metals, coal and oil before we have solved the problem of fusing hydrogen atoms. Similarly, disaster may follow if we press ahead too rapidly along particular lines in particular parts of the world without reference to the general welfare, and our distinction between primary and secondary needs must take increasing account of the human requirements in increased leisure. The risks of progress, Lord Adrian urged, should be calculated risks, based on two principles: our concern about the risk of serious disease rather than the risk of injury, and our concern that the human race should remain at least as healthy and intelligent as it is now.

Lord Adrian illustrated his point in a general way by referring to the radiation hazard. Thus he remarked that there will be many countries using nuclear power which may be less careful than ourselves in the disposal of radioactive wastes, and in seeing that fires and explosions do not generate clouds of radioactive material. Precautions taken in Britain will not necessarily protect us from the results of large-scale disasters elsewhere, and it is especially in the context of the aid to the under-developed countries that we should begin, as Lord Adrian suggested, to consider what risks a civilized community should regard as reasonable to accept. Indeed, as should already be apparent, the present risks which this age confronts arise largely out of the disparities which exist in the societies which constitute civilization, whether within or across national frontiers, and the stresses which such disparities in standards of living or in the capacity for adaptation and assimilation of technical advance are liable to cause. With the increasing attention now being focused on Western aid to the under-developed countries, either technical or economic, it is the more important that due thought should be given to this aspect, and that technical assistance should be considered realistically and impartially in its widest context.

STELLAR POPULATIONS

Stellar Populations

Proceedings of the Conference sponsored by the Pontifical Academy of Sciences and the Vatican Observatory, May 20–28, 1957. Edited by D. J. K. O'Connell, S.J. Pp. lxv + 544. (Castel Gandolfo: Specola Vaticana, 1958. Distributed by North Holland Publishing Company, Amsterdam; and Interscience Publishers, Inc., New York.) 76*s*.

THIS is not a text-book; neither is it merely a collection of independent papers on a common theme. It is the report of a successful conference held at the Vatican Observatory in 1957 on the complicated and rapidly changing problem of stellar populations.

The fundamental questions are how and when were the stars formed, how did the Milky Way come into being and what has determined its structure as we see it to-day? If we could sort out all the stars around us into groups or populations, according to age and origin, we should fairly certainly be much further on than now in our understanding of these larger questions. Only fifteen years have passed since Baade announced his now famous hypothesis that all stars belong to one of two families: Population I, the members of which are comparatively young, and are associated with interstellar matter and the spiral arms of galaxies; Population II, comparatively old and to be found in places where interstellar matter is scarce or non-existent, for example, the globular clusters, the elliptical galaxies, the nuclei of spiral nebulæ. Since then general opinion has come gradually to the view that the concept of two clear-cut populations is an over-simplification, and a good deal of time at this conference was taken up with producing a more acceptable scheme, not too elaborate in relation to the still very elementary nature of our knowledge.

The reader of "Stellar Populations", if he is to get much from the book, needs some idea of the underlying thoughts, not very explicitly described, which form the background of such discussions to-day. It is unlikely that all the participants had exactly the same picture in mind, and perhaps it is rash to attempt to put it into words. Although no fairy story, it could well start off with the familiar phrase 'once upon a time'; for the time-scale of the earlier stages of the Milky Way's history is still extremely uncertain.

Anyway, at this remote epoch there is supposed to have been a primitive diffuse gas of practically pure hydrogen. Somehow or other, by processes we do not properly understand, this gas condensed into first-generation stars (Baade's Population II), and at or about the same time the stars and gas condensed into a Milky Way system, not necessarily closely similar to our present Milky Way. This may have happened 5–10 thousand million years ago. The more massive of the first generation stars evolved rapidly, 'burned' their hydrogen into helium and later their helium into heavier elements. Theory shows us how this could happen, although only the fringe of the problem of computing the life-histories of appropriate star models has yet been tackled, but very significantly we have here a possible mechanism for the origin of the heavier elements. Some of the more rapidly evolving stars became unstable and either by catastrophic explosions or by shedding material from their outer layers (both processes can be observed to-day) 'enriched' the interstellar gas with helium and heavier elements as well as hydrogen. Afterwards there was more star-building from the interstellar gas. We are uncertain when this occurred, whether during critical periods when conditions were specially favourable, or at a more or less steady rate throughout the history of the Milky Way. We feel confident that some star formation has continued until astronomically very recent times, 1–10 million years ago (for Baade's Population I), and is probably still continuing to-day. During this history of perhaps 10^{10} years, the Milky Way evolved into the system we are now trying to explore by various techniques: a thin, flat, slowly rotating disk of stars and interstellar matter, with some spiral structure associated with dust, gas and young stars, and a more uniform background of older stars. The younger stars and the interstellar gas rotate in approximately circular orbits about the centre of the system; older stars tend to follow more elongated orbits, roughly elliptical, taking them at times near the centre. Around the centre older stars predominate and the system is supposed to have a nucleus and a central bulge similar to those we see in many external galaxies. Our picture includes also a very low-density halo, mainly gaseous but with a few stars, roughly spherical and for the most part detectable only by radio methods. The connexion of this halo with the rest of the system is so far not at all clearly understood.

Our ideas as to how all this came about are in detail till very vague. It is not unlikely that some essential arts of the problem have still eluded us, but so many different lines of evidence tend to point in the ame general direction that we are persuaded that oughly we are thinking along the right lines. The roblem of stellar populations is to sort out the stars as we see them to-day into some kind of an age order, and then to study their other physical properties in relation to this. We try to do this by using positions in the H–R. diagram, velocities, colour characteristics, or spectra, depending on what is available. The measurements are generally tedious, they often need large telescopes, and even when obtained the results may be inconclusive or ambiguous. Theoreticians have tasks as formidable as those of observers. For example, one of the conference members (Hoyle) estimated that something of the order of 10,000 hr. would be necessary on the largest existing electronic computers, to calculate the life-histories of a reasonably representative set of star models. Clearly, we are unlikely to get quick answers to any of the bigger questions, and since this kind of astronomical problem usually grows in complexity as our knowledge increases, the final answers may yet be a very long way off.

Meanwhile, here is a picture of the subject as it was in 1957, not a neat text-book account for a beginner, but a report of research in progress, with untidy ends everywhere, full of food for thought, but also capable of stirring up dissatisfaction, even irritation, in a critical reader. The organizers of this conference had the wisdom to keep it small. Among other great advantages this kept the discussions informal, spontaneous, well-informed and relevant. The reporting of both papers and discussions appears to have been done excellently.

R. O. Redman

HISTORY OF SCIENCE

A Short History of Scientific Ideas to 1900

By Dr. Charles Singer. Pp. xviii+525. (Oxford: Clarendon Press; London: Oxford University Press, 1959.) 35*s*. net.

WHEN Dr. Singer's "Short History of Science to the Nineteenth Century" appeared in 1941 it was the first, in the English language and within a reasonable compass, to "present, in simple form, the development of the conception of a rational and interconnected material world"; to relate the particular activity we call 'science' to the remaining intellectual activities of the heirs of Greco-Roman civilization. To emphasize the progressively changing character of that relationship the author introduced such leading phrases as "The Great Adventure" (Athens), "The Failure of Nerve" (Alexandria), "The Failure of Inspiration" (Rome), "The Failure of Knowledge" (Middle Ages), "The Revival of Learning", "The Insurgent Century", and "The Mechanical World". The present version—Dr. Singer rightly claims that it is "much more than a revision and rather more than a new edition"—contains in addition a succinct account (contributed by Dr. Angus Armitage) of the earliest records of systematized knowledge in the Middle East, and an additional Section—"Culmination of the Mechanical View of the World"—running to nearly 100 pages, rather less than half of which have been written by Prof. H. Dingle.

The book has been further enriched by two contributions by Dr. Derek Price, one on the work and instruments of Ptolemy, the other on the plane astrolabe. A few sub-sections, notably one on the "Status of Medieval Science", have been added, and others (for example, on the sixteenth century herbalists and anatomists) largely re-written. The importance of technological change is everywhere brought into greater prominence, and this is reflected among the much larger number of admirable illustrations, for the use of many of which, from "A History of Technology", Dr. Singer expresses gratitude to the Directors of Imperial Chemical Industries, Ltd.

The original "Short History", admirable as it was, could perhaps be criticized on the grounds of its sweeping condemnation of medieval science as a "period of intellectual degradation" (p. 161); the lack of balance in respect of the history of chemistry; and but a scant reference to embryology. Whereas the last lack has now been made good, it seems regrettable that, with the change of title and with the wealth of studies on the medieval period since the first appearance of the earlier version, the opportunity was not taken to present the medieval architects of ideas in a more sympathetic light. In regard to chemistry the situation has actually deteriorated. Though Prof. Dingle graciously allows that "the history of physics for a long time to come will not be without a chemical chapter" his ingeniously phrased "oraison funèbre", though not without expressions of profound respect for the departed, will scarcely pass as 'history'. Frankland did not just "assign" to each atom a property called valency; he was driven to speak (rather apologetically) of a "saturation capacity" in consequence of results unexpectedly obtained in his efforts to isolate a compound radical. To ignore the paths by which the Pisgah-views, now shared and interpreted by theoretical physicists, have been reached is to nullify a great deal of the cultural value of the history of science.

The faults, however, cannot outweigh the delight which awaits the reader in the many wise comments and illuminating comparisons scattered throughout the whole book. Perhaps, when in a few years time a third version is called for, the master from whom we have all learned so much might consider the dropping of the catch-titles. These may have been justified when first introduced ; but has not the time now come when a history of science should place the emphasis on *wie es eigentlich gewesen* ?

WILLIAM P. D. WIGHTMAN

AGRICULTURAL RESEARCH IN INDIA

Agriculture and Animal Husbandry in India

By Dr. M. S. Randhawa. Pp. xvi + 364. (New Delhi : Indian Council of Agricultural Research, 1958.) Rs. 15.00.

Mechanical Cultivation in India

By D. A. Gadkary. Pp. ix + 147 + 10 plates. (New Delhi : Indian Council of Agricultural Research, 1957.) Rs. 7.25 ; 11*s*. 6*d*.

AGRICULTURAL research in India is a subject of such importance that it is scarcely an exaggeration to say that the future of the world may depend upon it. Indian scientists and the Indian Council of Agricultural Research have had quite a good record so far, though both the financial and human resources of India fall far short of the real requirements of the situation. As Dr. Randhawa freely admits, other countries faced with the problem of obtaining maximum food supply from a limited area—Japan, Italy and Egypt—obtain yields per acre three or four times India's. If India could raise her yields to these levels she could over-feed any conceivable population she is likely to have for a very long time to come. But mere transplantation of seeds, fertilizers and methods of cultivation from, say, Japan, will not suffice. Plant breeding, as optimistic farmers have found to their cost, is a laborious task which has to be done over again for even the slightest difference in climate, and then again as new pests appear.

"Agriculture and Animal Husbandry in India" does not deal with the problems on the actual frontier of research, though the compilers are clearly aware of them. It is a compendium of information on the best strains of plants now available, cultivation requirements, expected yields, and where the seeds can be obtained. The geographical maps and statistical tables have been well done, though the chapter on irrigation is disappointingly superficial, and livestock receive much less attention than crops.

For every scientist engaged in original agricultural research India will need perhaps a hundred men to disseminate his results, as well as the elements of agricultural science, among an uninformed people. A book like this should play a valuable part in their training, and be a useful reference book to librarians in other countries.

"Mechanical Cultivation in India" is not broad enough in its scope to constitute an economic study of the circumstances (admittedly limited) in which mechanical cultivation is now worth introducing in India. Nor is it detailed enough to serve as an operator's handbook. It appears to have been designed more as an administrative handbook, imparting the necessary minimum of information about types of machines, and making preparations for the administrative, recording and accounting duties which will arise if mechanical implements are to be operated from governmental tractor stations.

COLIN CLARK

INDUSTRIAL GUMS

Industrial Gums

Polysaccharides and Their Derivatives. Edited by Roy L. Whistler and James N. BeMiller. Pp. xi + 766. (New York : Academic Press, Inc. ; London : Academic Press, Inc. (London), Ltd., 1959.) 25 dollars.

BRIDGING the gap between the academic chemist and the chemical technologist is always a problem since in general their points of view differ widely. Here it has been achieved by competent academic editing of a series of chapters written mainly by industrial chemists. The brief 'academic' chemistry of gums included in the book does not interfere, and is indeed necessary, for the main task of presenting detailed information of those practical applications of gums which are of particular interest to food technologists, paint and textile manufacturers, paper industrialists and pharmaceutical chemists. The current prices and potential resources of man of the gums are included. Certain gums which, as ye have not been used widely in industry are include together with suggestions as to their possible applic tions.

My minor criticisms of this book include a lack consistency from one chapter to another in depicti of polysaccharide structures and indeed their co plete absence in certain chapters. In the otherwis competent chapter on dextran I could find no details of the Swedish manufacture of dextran or of the use of iron complexes of dextran. The author was also unaware that the structure of the mycodextran from *Aspergillus niger* (p. 552) had been extensively investigated and that it had been renamed nigeran, due to its marked structural difference from normal dextrans. The more detailed formula for laminaran postulated by Peat and his colleagues could well have been included. In the chapter on agar no mention is made of its application in the now widely used agar diffusion technique. The authors of the agar article are employed by the only American company manufacturing agar, and can perhaps be forgiven for advertising the superiority of their company's product as opposed to that of the much cheaper Japanese agar. The book gives detailed coverage of the literature up to the end of 1957 with scattered references from 1958.

I can thoroughly recommend this book as essential for all technical libraries, providing as it does comprehensive references to the numerous patents on the industrial uses of gums. I am sure it will be read more widely than its title suggests, since by analogy numerous applications can be suggested for many unexploited polymers, particularly as attempts are made throughout the book to relate the physical characteristics of the gums to their chemical structure. After editing this book, Prof. Whistler will be much sought after as an industrial consultant.

S. A. BARKER

Radioisotopes in Scientific Research

Proceedings of the International Conference held in Paris in September 1957, under the auspices of the United Nations Educational, Scientific and Cultural Organization. Edited by Prof. R. C. Extermann. Vol. 1: Research with Radioisotopes in Physics and Industry. Pp. xxi+761. Vol. 2: Research with Radioisotopes in Chemistry and Geology. Pp. xxi+741. (London and New York: Pergamon Press, 1958.) 140*s.* net each volume.

THE Unesco Conference on "Radioisotopes in Scientific Research" has been reported in *Nature*, **180**, 1029 (1957). The proceedings, which have now been published, comprise the contributions in their original language, but the abstracts of each paper are given in English, French, Russian and Spanish. The discussions are reported for each paper, and, although greatly reduced in volume, are well edited. Contrary to general belief that such research outdates itself in a reasonably short time, one has to admit that some of the material presented will be extremely useful to workers in this field for many years to come. For example, the work reported on the tracing of water by using cosmic-ray and man-made tritium, by Begemann and Libby, is only now fully appreciated, and work in years to come will be based on the ideas contained in this paper. The proceedings of this most useful conference should certainly be in every science library and, to a certain extent, they can be regarded as reference books.

Although the reproduction and printing are reasonable, if not in any way elaborate, the price of the volumes seems rather high. It is a pity that the book, which came out one year after the conference was held, still contains a number of misprints, the most misleading ones being found in the index of Vol. 2, where twenty-two contributions have been indexed with the wrong page number owing to the fact that one contribution was erroneously split in two, whereas at the end of the book the page number again agrees with that of the papers, because one page number was left out for one contribution altogether.

H. SELIGMAN

Nitrogen Metabolism in Plants

By Prof. George C. Webster. (Row–Peterson Biological Monographs.) Pp. viii+152. (Evanston, Ill.: Row, Peterson and Company, 1959.) 3.50 dollars.

THIS is an age in which authoritative reviews in the fields of plant physiology and plant biochemistry are tending to be concentrated in encyclopædias or other massive volumes which are too expensive for individual ownership; indeed, the influence of such compilations on scientific thought may prove to be limited because of the physical difficulty of consulting them. Thus, there is still very much room for smaller publications in which substantial fields of investigation are reviewed authoritatively and, though not exhaustively, with sufficient documentation for the reader to be made aware of the more important original sources. Such a review is provided by this very useful little book, which is concerned mainly with the chemical pathways of nitrogen metabolism in plants and has been written by an author who is already well known for his own original studies in this field. The topics covered are nitrogen nutrition, amino-acid metabolism, biosynthesis of amides and peptides, protein and nucleic acid metabolism, nitrogen metabolism of excised organs and ageing tissues, and translocation of nitrogenous substances. The book is written in straightforward and clear style, marred only occasionally by infelicitous phrases or repetitive treatment. In a few instances (for example, Table 2) the identity of the plant material to which the data presented refer is not stated; three misprints were noted, while an arrow appears to be missing from Fig. 26. These are minor blemishes in an otherwise workmanlike text, which I recommend for use by research workers and honours students.

G. BOND

Bird Watching for Beginners

By Bruce Campbell. (Puffin Book PS71.) Pp. 240. (Harmondsworth, Mddx.: Penguin Books, Ltd., 1959.) 2*s.* 6*d.*

THIS is a revised edition of a book first published in 1952. It is divided into three sections. The first explains how to become a bird watcher and the limits of classification. The second discusses two hundred common British resident and visiting species in systematic order from crows to game-birds. It deals mainly with relationships, distribution and habits, and points out aspects "suitable for study by the ordinary bird watcher".

Part 3 briefly surveys various problems; how to set about identification, how to make bird counts, how to study birds at the nest, and so on.

The author is highly qualified to give instructions to beginning bird watchers. He has an extensive practical knowledge of field-study and his association with the British Trust for Ornithology has given him a wide background of the subject based on the experience of others. Ability to impart this knowledge has been gained from long practice as lecturer and broadcaster. He has a readable style and pleasing personal approach which not only provides information but also inspires enthusiasm.

J. D. MACDONALD

The Rhondda Valleys

A Study in Industrial Development, 1800 to the Present Day. By E. D. Lewis. Pp. xiii+312+3 plates. (London: Phoenix House, Ltd., 1959.) 25*s.* net.

THE Rhondda became a borough in 1955 and to mark the event sponsored the publication of this excellent local history. Begun twenty years before as a master's thesis for the University of Wales, its author, the son of a Rhondda collier and now a Rhondda headmaster, has expanded his work to a scholarly and well-documented local history. The story of the Rhondda is well known, being that of a sparsely populated, picturesque, well-wooded valley, rarely penetrated by strangers at the beginning of the nineteenth century; it passed through a whole cycle of industrial development within the next hundred years, to be hit with more than average severity by the depression following the First World War. What would perhaps, in another continent and another context, have become a ghost town as its *raison d'être* faded, had too great a reservoir of human vitality to succumb. Much of the book is devoted to the human story—the early working conditions, the rise and temporary fall of trade unionism, and the later role of the Rhondda as stormy pioneer and leader in new concepts of management and labour relationships. The final chapter, dealing with the period from 1914 to the present day, makes it clear that the story is far from ended.

L. DUDLEY STAMP

STRUCTURE OF HÆMOGLOBIN

A THREE-DIMENSIONAL FOURIER SYNTHESIS AT 5·5-Å. RESOLUTION, OBTAINED BY X-RAY ANALYSIS

By DR. M. F. PERUTZ, F.R.S., DR. M. G. ROSSMANN, ANN F. CULLIS, HILARY MUIRHEAD and DR. GEORG WILL
Medical Research Council Unit for Molecular Biology, Cavendish Laboratory, University of Cambridge
AND
DR. A. C. T. NORTH
Medical Research Council External Staff, Davy Faraday Research Laboratory, Royal Institution, London, W.1

VERTEBRATE hæmoglobin is a protein of molecular weight 67,000. Four of its 10,000 atoms are iron atoms which are combined with protoporphyrin to form four hæm groups. The remaining atoms are in four polypeptide chains of roughly equal size, which are identical in pairs[1-3]. Their amino-acid sequence is still largely unknown.

We have used horse oxy- or met-hæmoglobin because it crystallizes in a form especially suited for X-ray analysis, and employed the method of isomorphous replacement with heavy atoms to determine the phase angles of the diffracted rays[4-7]. The Fourier synthesis which we have calculated shows that hæmoglobin consists of four sub-units in a tetrahedral array and that each sub-unit closely resembles Kendrew's model of sperm whale myoglobin[6]. The four hæm groups lie in separate pockets on the surface of the molecule.

Method of Analysis

Horse oxyhæmoglobin, crystallized from 1·9 *M* ammonium sulphate solution at *p*H 7, has the space group *C*2 with two molecules in the unit cell which lie on dyad axes[8]. In order to determine the phase angles of the 1,200 reflexions contained in the limiting sphere of 5·5 Å.$^{-1}$, six different isomorphous heavy-atom compounds were used (ref. 9 and unpublished work). Intensities were measured photographically and by counter spectrometer (Arndt, U. W., and Phillips, D. C., unpublished work). The relative positions and shapes of the heavy-atom replacement groups were found by correlation functions based on Patterson methods[10] and refined by least squares procedures. For each reflexion the structure amplitudes of all seven compounds were combined in an Argand diagram[11], and the probability of the phase angle having a value α was calculated for α = 0 10, . . . 355°. The centroid of the proba bution, plotted around a circle, was the the best vector *F* in the Fourier synth ...e results were finally plotted on 32 con ...r maps showing the distribution of electron density in sections spaced 2 Å. apart normal to *b* (Fig. 1). The absolute configuration of the molecule was determined from anomalous dispersion[4].

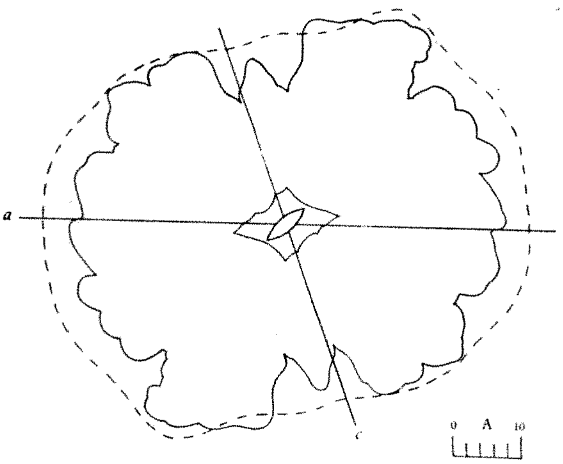

Fig. 2. External shape of the molecule. Full lines indicate the boundary derived from the contour at 0·54 electron/Å.^{3}. The broken line shows the boundary derived by Bragg and Perutz from two-dimensional data (ref. 13). Note the hole in the middle

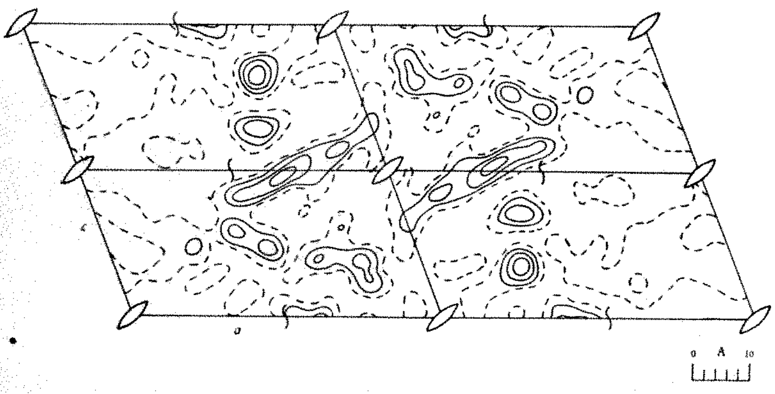

Fig. 1. Section at $y = 1/32b$. This cuts through the middle of the molecule on which the diagram is centred. 'Flat' areas indicating liquid appear on the left and right. Contours are drawn at intervals of 0·14 electron/Å.^{3}. The broken line marks 0·4 electron/Å.^{3}. Contours at lower levels are omitted

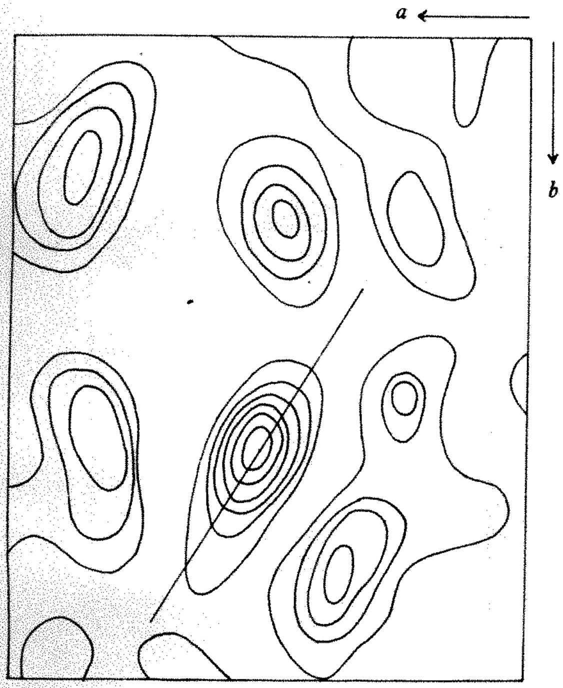
External Shape of the Molecule

More than half the volume of the crystals is taken up by liquid of crystallization, which mainly fills the spaces between the molecules and shows up on the contour maps in the form of flat, featureless regions (Fig. 1). The outlines of the two molecules in the unit cell can be traced by following the boundaries between these regions and the continuous electron-dense regions described below. In Fig. 2 the outline of one molecule, traced from the periphery of the 0·54



Hæm 1 and 2

Fig. 3. Section at $z = 1/4\ c$ showing one of the two hæm groups in the asymmetric unit. The straight line indicates the hæm orientation derived from electron spin resonance (ref. 14). The lowest contour shown is at 0·4 electron/Å.^{3}

electron/Å.^{3} contour, is seen in projection on the *b*-plane. To a first approximation it can be regarded as a spheroid with a length of 64 Å., a width of 55 Å. and a height of 50 Å. normal to the plane of the paper. Except for a slight shortening along *a*, this shape agrees with the earlier picture obtained from two-dimensional data, even including the dimple in the centre of the molecule (see Fig. 2 of ref. 12).

Positions of the Hæm and Sulphydryl Groups

Four peaks stand out from the rest, clearly representing the iron atoms with their surrounding porphyrin rings. A flattening of the peaks indicates the approximate orientation of the rings (Fig. 3). Fortunately, their exact orientation was already known from electron spin resonance[14], and it only remained to assign the correct one of the four alternative orientations of the hæms to each of the electron density peaks. The results are shown in Fig. 4. The iron atoms lie at the corners of an irregular tetrahedron with distances of 33·4 and 36·0 Å. between symmetrically related pairs. The closest approach between symmetrically unrelated iron atoms is 25·2 Å. (Table 1).

Table 1

	Fe_1	Fe_3	S_1
x	−6·6 Å.	12·3 Å.	5 Å.
y	7·3 Å.	−10·7 Å.	10 Å.
z	13·1 Å.	18·2 Å.	16 Å.

$Fe_1 - Fe_2 = 33{\cdot}4$ Å.
$Fe_3 - Fe_4 = 36{\cdot}0$ Å.
$Fe_1 - Fe_3 = 25{\cdot}2$ Å.
$Fe_1 - S_1$ 13 Å.
$Fe_3 - S_1$ 21 Å.

Horse hæmoglobin contains four cysteine residues, but only two sulphydryls combine with mercury in the native protein[5]. From the positions of the mercury atoms we inferred that each of the two sulphydryl groups is about 13 Å. away from one iron atom and 21 Å. away from another. (Fig. 4 and Table 1). The significance of this situation is discussed below.

Configuration of the Polypeptide Chains

The most prominent feature of the Fourier synthesis consists of more or less cylindrical clouds of high density, like the vapour trails of an aeroplane; they are curved to form intricate three-dimensional figures. Sections through various parts of these appear in Fig. 1. To build a model of the figures, we rolled out sheets of a thermo-setting plastic to the thickness of our sections on a scale of 2 Å. = 1 cm., and cut out the shape of each region on the contour maps where the density exceeds 0·54 electron/Å.^{3} (this corresponds to the first full contour line in Fig. 1. From this section, for example, 14 shapes would be cut). The shapes were then assembled in accordance with their positions and heights in the different sections, and the hæm groups were attached in the appropriate orientation. The model was then baked to set it permanently. For comparison, a Fourier synthesis of sperm whale myoglobin was calculated at a resolution of 5·5 Å., using the new X-ray data of Kendrew *et al.*[15], and a model of the electron density distribution was constructed by the method just described.

From the hæmoglobin Fourier synthesis there emerged four separate units which are identical in pairs. Fig. 5 shows one member of each pair together with the model of myoglobin on the left. In each unit the cloud of high density describes a complicated figure which, in the white unit (middle), can be traced from end to end by following the superimposed line. Except for two small gaps where the density sinks slightly below 0·54 electron/Å.^{3}, the black unit (right) closely resembles the white one. There are several gaps interrupting the myoglobin model where, probably due to increased thermal motion, the electron density falls below the contour-level chosen for cutting the model. However, we know from the recent work of Kendrew and his collaborators[15] that

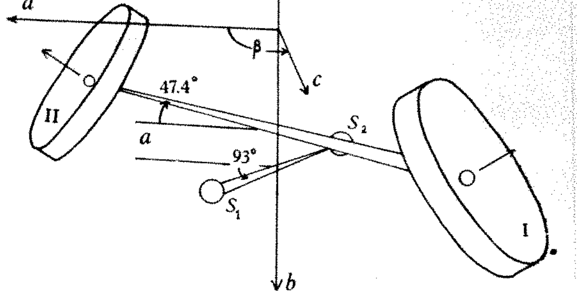


Fig. 4. Arrangement of hæm groups in hæmoglobin. Arrows indicate the reactive side of each group. The *c*-axis comes out of the paper towards the observer. This picture and all subsequent ones show the absolute configuration

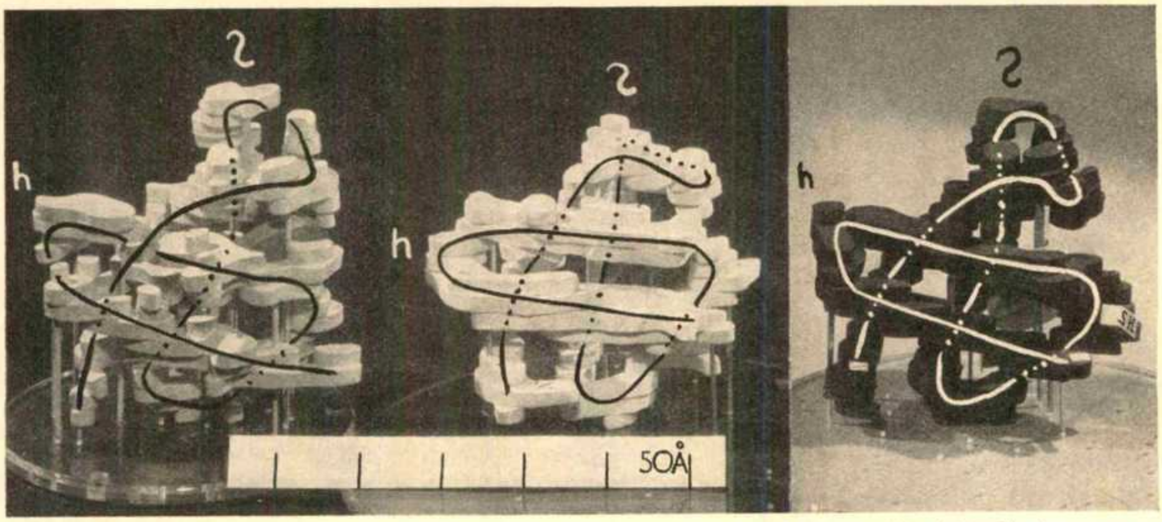

Fig. 5. Two different polypeptide chains in the asymmetric unit of hæmoglobin compared with myoglobin (left). The hæm groups are at the back of the chains

the gaps are bridged by a continuous polypeptide chain, and it is evident from Fig. 5 that apart from the gaps, the model has a configuration closely similar to the hæmoglobin units.

Clearly, the four tortuous clouds of high electron density in hæmoglobin represent the four polypeptide chains. The black and the white chains have similar, but not identical configurations. In the black chain the *S*-shaped bend at the top is more pronounced, the hæm group is lower, and the bend *h* sharper than in the white chain. These, however, are details. The most important result is their resemblance to each other and to sperm whale myoglobin.

Arrangement of the Four Sub-units

The first step in the assembly of the molecule is the matching of each chain by its symmetrically related partner (Fig. 6). It will be noted that there is comparatively little contact between the members of each pair, suggesting rather tenuous linkages. In the next step the white pair is inverted and

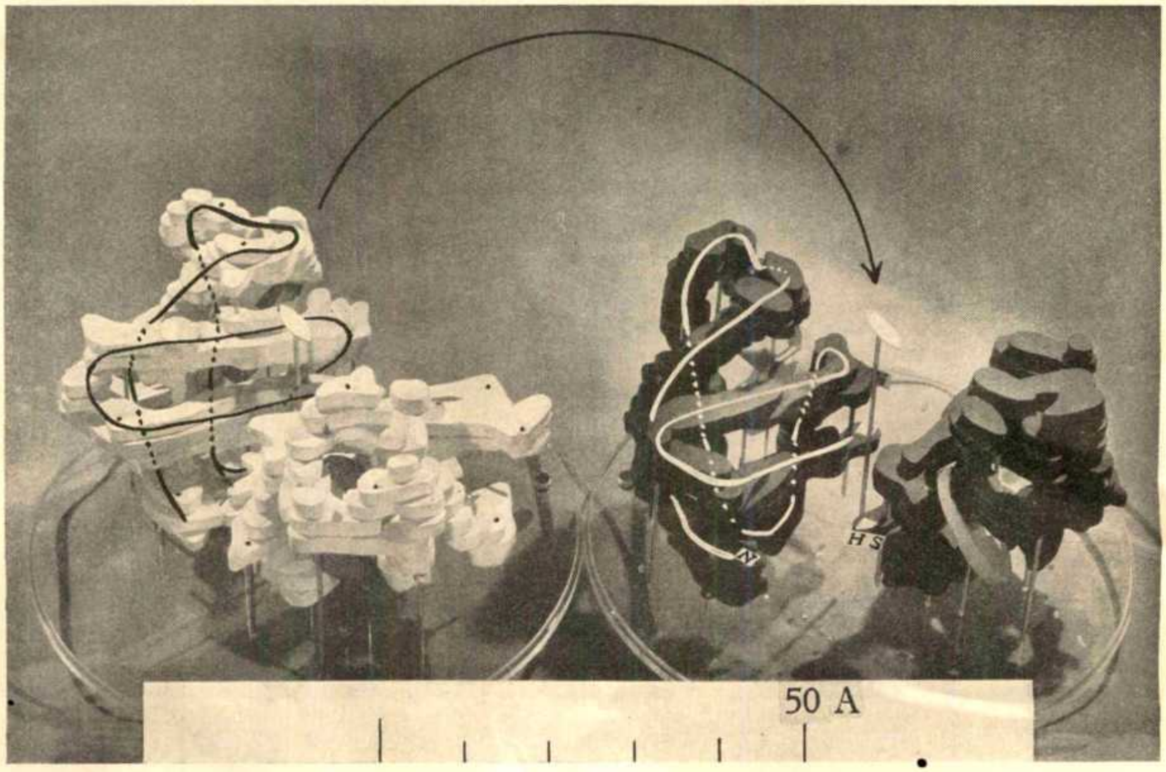

Fig. 6. Two pairs of chains symmetrically related by the dyad axis. The arrow shows how one pair is placed over the other to assemble the complete molecule

placed over the black pair as indicated by the arrow. Fig. 7 shows one white chain placed over the pair of black ones and Fig. 8 shows the molecule completely assembled. The resulting arrangement is tetrahedral and has almost, but not quite, the orthorhombic point group symmetry 222. It contains two 'pseudo dyads' which lie approximately at right angles to each other and to the true dyad, one emerging from the centre of Fig. 8 and the other from the centre of Fig. 9. This means that, to a first approximation, each sub-unit can be generated by a rotation of 180° from any of its neighbours. Figs. 7, 8 and 9 also show that the surface contours of the white chains exactly fit those of the black, so that there is a large area of contact between them. This structural complementarity is one of the most striking features of the molecule. Fig. 10 is a view down the true dyad axis and reveals a hole going right through the centre of the molecule, as was to be expected from the Fourier projection[13]. However, the van der Waals radii of the chains are much bigger than appears in the model, and little room may, in fact, be left for water or electrolytes to pass through. Fig. 10 also reveals a dimple at the top where the white chains meet. This is matched by a similar, but larger, hollow at the bottom where the black chains meet.

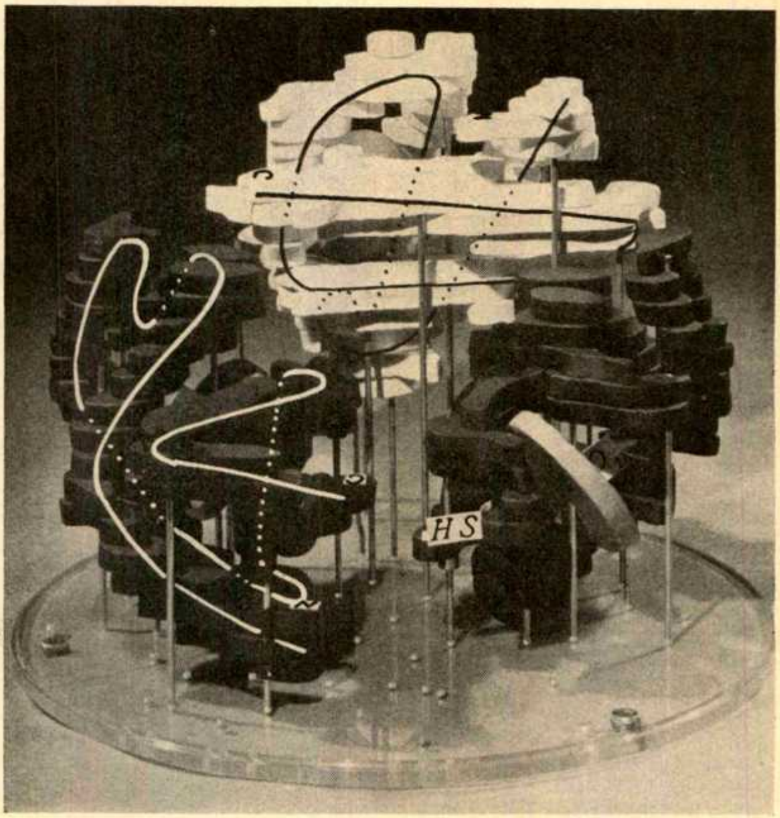

Fig. 7. Partially assembled molecule showing two black chains and one white

The hæm groups are seen to lie in separate pockets on the surface of the molecule (Fig. 8). Each pocket is formed by the folds in one of the polypeptide chains, which appears to make contact with the hæm group at four different points at least. The iron atoms in the neighbouring pockets formed by the black and the white chains are 25 Å. apart.

Information from the Fourier Synthesis of Myoglobin at 2-Å. Resolution (ref. 15)

Thanks to the similarity with myoglobin, the interpretation can be carried further than would have been possible on the basis of our results alone. Kendrew *et al.* have found that the straight stretches of rod indicated in Fig. 5 are α-helices and that the N-terminal end of the chain is at the bottom left. The ends of the two hæmoglobin chains have been labelled *N* and *C* accordingly, as seen in Figs. 7 and 10. The myoglobin Fourier synthesis also reveals the hæm-linked amino-acid side-chain, probably histidine, on one side of the (ferric) iron atom and a small peak, probably representing a water molecule, on the other side. If this information is transferred to hæmoglobin, the reactive side of the hæm group is as indicated by the arrows in Fig. 4 and by the labels O_2 in Figs. 7 and 8*a*.

Figs. 7 and 8*b* show the reactive sulphydryl group (which is absent in myoglobin) to be attached to the portion of the black chain carrying the hæm-linked histidine. It is seen that the histidine and cysteine side-chains point in roughly opposite directions, one towards and the other away from the hæm group. The sulphydryl group may possibly be in contact with the loop of the white chain which lies below the hæm group on the left. This is the situation of one pair of sulphydryl groups in the molecule. The second pair is probably attached to the white chains, but it is unreactive in the native protein and its position is still unknown.

Reliability of Results

The method of isomorphous replacement makes no assumptions about the structure of the protein, and its results suffer from none of the ambiguities which bedevil the interpretation of vector maps. Ideally, the parent protein, in combination with two different isomorphous heavy-atom compounds, should give accurate phase angles and electron density maps which are free from all except series termination errors. In practice, errors and uncertainties arise from several sources and must be minimized by using more than two heavy-atom compounds. In our case it was possible to estimate the accuracy of the phase angle for each reflexion from the measure of agreement between the angles indicated by the six different compounds. From the standard error in the vector *F*, averaged over all reflexions, the standard error in the final electron density was calculated as $0\cdot12$ electron/Å.^{3}, which amounts to $0\cdot85$ of the interval between successive contours in Figs. 1 and 3 ($0\cdot14$ electron/Å.^{3}), or $0\cdot15$ of the difference in density between 'peaks' and 'valleys' ($0\cdot7$ electron/Å.^{3}) (ref. 12). This calculated error is borne out by the observed fluctuations in the liquid regions between the molecules and by the difference in height between the two iron peaks ($0\cdot13$ electron/Å.^{3}).

An error of at least five times this magnitude would be needed to turn a peak into a valley and thus to simulate the backbone of a polypeptide chain in a region actually occupied by side-chains.

Normally, the accuracy of a structure is checked by comparison of calculated and observed intensities. In hæmoglobin this is impossible so long as the light atoms are not resolved, but the positions of the iron atoms at least can be checked by their anomalous dispersion effect. Depending on the phase relationship between the structure factor of the four iron atoms by themselves and that of the entire molecule, the total intensity of any given reflexion $I\ (hkl)$ may be larger or smaller than $I\ (\bar{h}\bar{k}\bar{l})$. We selected 50 reflexions for which the effect of anomalous dispersion was expected to be largest and measured the intensity of each reflexion in the four symmetrically related quadrants on the counter spectrometer. Statistically significant differences between $I(hkl)+I(\bar{h}k\bar{l})$ and $I(\bar{h}\bar{k}\bar{l})+I(h\bar{k}l)$ were found in 36 reflexions. In 34 of them the signs of the differences agreed with prediction, indicating that the phase angles of the reflexions as well as the positions of the iron atoms are correct.

As a further check on the positions of the iron atoms, an attempt was made to label them with heavy atoms. This was done by allowing crystals of methæmoglobin, which are isomorphous with oxyhæmoglobin, to react with *p*-iodophenyl–hydroxylamine, which attaches itself to the iron atoms. A difference Fourier projection on the *b*-plane showed four prominent peaks which lie well within the calculated distances between the iodine and the iron atoms.

Finally, to avoid any possible bias in the interpretation of the Fourier synthesis, we have tried to construct objective models containing only those features actually found in the electron density maps. Due to series termination errors and inaccuracies in many of the phase angles, these maps must certainly contain errors of detail. Large errors, on the other hand, are unlikely because, quite apart from the checks just described, the results really prove themselves. No combination of errors could have led to the appearance of four distinct chains of roughly equal length, in agreement with chemical evidence, to the similarity between the two pairs of chains which are not related by crystal symmetry, and to the resemblance between hæmoglobin and myoglobin.

Discussion

The polypeptide chain-fold which Kendrew and his collaborators first discovered in sperm whale myoglobin has since been found also in seal myoglobin[16].

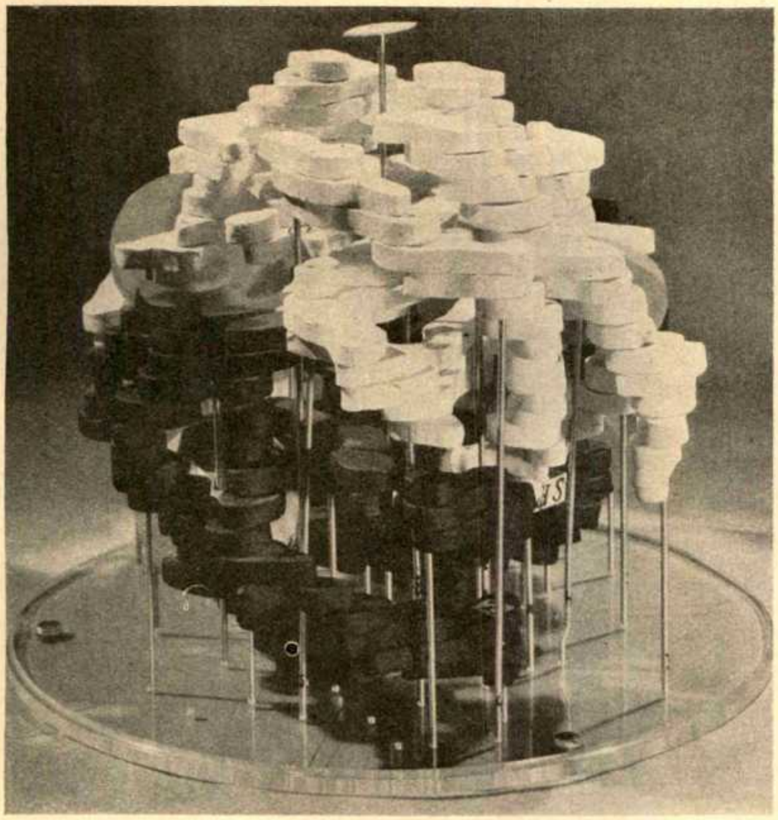

Fig. 9. Hæmoglobin model viewed normal to *c*

Its appearance in horse hæmoglobin suggests that all hæmoglobins and myoglobins of vertebrates follow the same pattern. How does this arise ? It is scarcely conceivable that a three-dimensional template forces the chain to take up this fold. More probably the chain, once it is synthesized and provided with a hæm group around which it can coil, takes up this configuration spontaneously, as the only one which satisfies the stereochemical requirements of its amino-acid sequence. This suggests the occurrence of similar sequences throughout this group of proteins, despite their marked differences in amino-acid content. This seems all the more likely, since their structural similarity suggests that they have developed from a common genetic precursor.

Little can be said as yet about the relation between structure and function. The hæm groups are much too far apart for the combination with oxygen of any one of them to affect the oxygen affinity of its neighbours directly. Whatever interaction between the hæm groups exists must be of a subtle and indirect kind that we cannot yet guess. A few observations of possible significance might be mentioned. Kendrew found that the combination of reduced myoglobin with oxygen involves no structural changes detectable by X-ray analysis[17], both forms being isomorphous with the metmyoglobin normally studied. In the hæmoglobin of horse and of man, on the other hand, the oxygenated and reduced forms are crystallographically different[18-20]. The structure of reduced hæmoglobin is still unknown, but it would not be surprising if loss of oxygen caused the four sub-units to rearrange themselves relative to each other, rather than to change their individual structure to a marked degree.

Riggs has shown that blocking the sulphydryl groups reduces hæm–hæm interaction[21]. As Fig. 8 shows, these groups occupy key positions close to the hæm-linked histidines and to points of contact between two different sub-units. They may well play an important part in the transition between the oxygenated and reduced forms. Incidentally, the cysteine residue should provide a convenient marker for the peptide containing the hæm-linked histidine, and so help to determine the sequence in this important part of the chain.

A full account of this work will be published elsewhere.

We thank the Director and staff of the University of Cambridge Mathematics Laboratory for making their electronic computor *Edsac* II available to us for the many calculations involved in this work. We are

STRUCTURE OF MYOGLOBIN

A THREE-DIMENSIONAL FOURIER SYNTHESIS AT 2 Å. RESOLUTION

By DRS. J. C. KENDREW, R. E. DICKERSON, B. E. STRANDBERG, R. G. HART
and D. R. DAVIES*
Medical Research Council Unit for Molecular Biology, Cavendish Laboratory, Cambridge
AND
D. C. PHILLIPS and V. C. SHORE
Davy Faraday Laboratory, The Royal Institution, London

MYOGLOBIN is a conjugated protein consisting of a single polypeptide chain of about 153 amino-acid residues associated with an iron–porphyrin complex, the hæm group; its molecular weight is about 18,000, and the molecule contains some 1,200 atoms (excluding hydrogen). Two years ago a preliminary report of the first stage of an investigation of the three-dimensional structure of sperm-whale myoglobin was published in *Nature*[1] (a detailed account of this work has appeared recently[2]). Several isomorphous crystalline derivatives of myoglobin containing heavy atoms (mercury or gold) at single sites on the molecule were prepared, and by comparing the X-ray diffraction patterns of these crystals with those of the unsubstituted protein, it was possible to deduce the phases of all the reflexions in the X-ray pattern having spacings greater than 6 Å. These phases, together with the observed amplitudes, were used to compute a three-dimensional Fourier synthesis of the electron density in the unit cell (which contains two molecules) at a resolution of 6 Å. In this synthesis the polypeptide chain was visible as a rod of high electron density, folded in a complex pattern (Fig. 5*a*); in addition, the single hæm group with its iron atom, which is much more dense than any other atom in the molecule, could be identified as a disk of high electron density. The shape of the molecule could be determined with some confidence, as could most of the course of the single polypeptide chain, though there were several ambiguities where it turned through a large angle, so that the ends of the chain could not be located with certainty. Thus, the general nature of the tertiary structure of the molecule was revealed, but not the secondary structure of the polypeptide chain, though the results were consistent with a helical configuration.

More recently, Scouloudi[3] used similar methods to obtain a two-dimensional Fourier projection of the unit cell of seal myoglobin, in which the molecular arrangement is entirely different from that in sperm-whale crystals; she was able to show that the myoglobins of these two species have essentially the same tertiary structure in spite of their different amino-acid compositions. Her work, by implication, confirmed the correctness of both analyses, as well as the deductions made about the shape of the molecule. In the accompanying article[4] Perutz *et al.* now describe a three-dimensional analysis of the related protein hæmoglobin, at a slightly greater resolution, and show that each of the four sub-units of which this molecule is composed bears a close structural resemblance to myoglobin. It is apparent, therefore, that sperm-whale myoglobin possesses a structure the significance of which extends beyond a particular species and even beyond a particular protein.

We now present the results of a second stage in the analysis of sperm-whale myoglobin; in this the resolution has been increased to 2 Å., that is to say, not far short of atomic resolution. The resulting Fourier synthesis is very complicated, and a detailed study of it will take many months; in the meantime, our preliminary findings may be of interest.

Methods of X-ray Analysis

In this stage we have simply extended the methods which proved successful in the first stage of the analysis, comparing the diffraction pattern of unsubstituted myoglobin crystals with those of the *p*-chloromercuribenzene sulphonate, mercury diammine and aurichloride derivatives, together with a double derivative containing the first two substituents simultaneously. Whereas myoglobin crystals give 400 reflexions having spacings greater than 6 Å., the number of reflexions with spacings greater than 2 Å. is 9,600, each of which has to be measured not only for the unsubstituted protein but also for each of the derivatives. The very much greater number of data posed many problems, both in recording intensities and in computation, and in this stage we relied much more heavily than before on the use of a high-speed computer; it was fortunate that about the time the work began the *Edsac* Mark I computer used previously was superseded by the very much faster and more powerful Mark II.

---

* Visiting scientist from the National Institute of Mental Health, Bethesda, Md.

The data for each derivative were recorded on twenty-two precession photographs; a separate crystal had to be used for each photograph to keep radiation damage within acceptable limits. The results from the different photographs were scaled together on the computer, the best set of scaling factors being determined by solving an appropriate 22 × 22 matrix[5]. The degree of isomorphism of each derivative was tested, and found adequate, by means of a computer programme which used the *h0l* reflexions to refine the preliminary values of the heavy-atom parameters, temperature factor, etc., and then compared the values of $\delta F_{\text{obs.}}$ and $\delta F_{\text{calc.}}$ as a function of $\sin\theta$. The co-ordinates of the heavy atoms were further refined using correlation functions[6] computed by means of programmes devised by Dr. M. G. Rossmann, and finally refined again during the process of phase determination itself. The phases were determined by essentially the same method as before, but owing to the very large number of reflexions the determination was carried out on the computer rather than graphically. The 'best' phases and amplitudes[7] were computed and used in the final Fourier synthesis, to which a moderate degree of sharpening was applied. In all, some hundreds of hours of computer time were required, and the Fourier synthesis itself, which was calculated at intervals of about 2/3 Å., took about 12 hr.

The Fourier Synthesis

The electron density distribution was plotted in the form of 96 sections perpendicular to x^* and spaced 2/3 Å. apart, the density in each section being represented by a series of contours. For some purposes this method of representation is unsatisfactory, and we have also constructed models of parts of the structure on a scale of 5 cm. = 1 Å., by erecting vertical steel rods parallel to y in an array corresponding to the grid of points in the xz-plane at which densities were calculated, the value of the electron density at points along the rods being indicated by coloured clips. On this scale the whole molecule is about 6 ft. cube, and about 2,500 rods each 6 ft. high are required (see Fig. 4).

The distance between singly bonded carbon atoms is 1·54 Å.; many of the common types of covalent bond present in protein molecules are shorter than this. We could not expect, therefore, that neighbouring covalently bonded atoms would be resolved in the present Fourier synthesis, and in fact such resolution was not achieved; on the other hand, the degree of resolution actually obtained is very nearly as great as theory would indicate, showing that the errors in the synthesis cannot be very large (see Fig. 2). The distances between neighbouring groups in Van der Waals contact is of the order of 3 Å., however, and as would be anticipated, we find that such groups appear as discrete regions of high density. One factor which complicates the interpretation is that similar groups (for example, peptide bonds) in different parts of the structure have substantially different densities. We attribute these differences to variation in the amplitude of thermal vibration in different parts of the molecule. Thus the terminal amino-end of the chain, which is on the outside of the molecule, has low density and is presumably relatively flexible; on the other hand, structures near the hæm group, which is surrounded by several segments of polypeptide chain running in different directions, possess high density, presumably because this part of the molecule is stabilized by many inter-chain bonds.

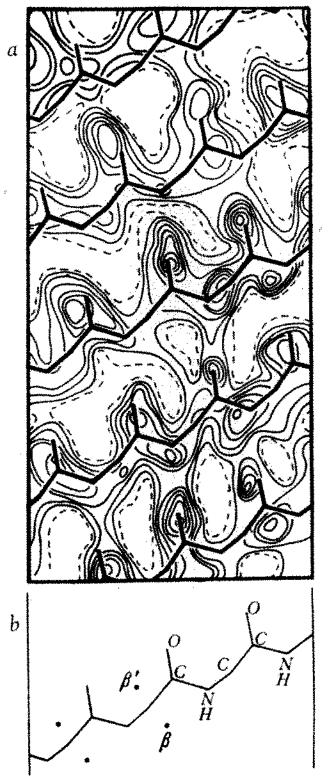

Fig. 1. (*a*) Cylindrical projection of a helical segment of polypeptide chain, with the α-helix structure superposed: for explanation see text. (*b*) Key to the atomic arrangement in the α-helix. The points marked β and β′ are the two alternative projected positions of C_β; β is the position in a right-handed and β′ that in a left-handed helix of L-amino-acids

Configuration of the Polypeptide Chain

In the 6-Å. Fourier synthesis the polypeptide chain appeared as a solid rod of high density with approximately circular cross-section; segments of the chain were more or less straight, and these were joined by dense regions where the chain turned corners. In the 2-Å. synthesis all the straight segments of chain were found to be hollow cylindrical tubes of high density; projecting at intervals from the cylindrical core are dense regions of various shapes and sizes, which are clearly the amino-acid side-chains. More detailed

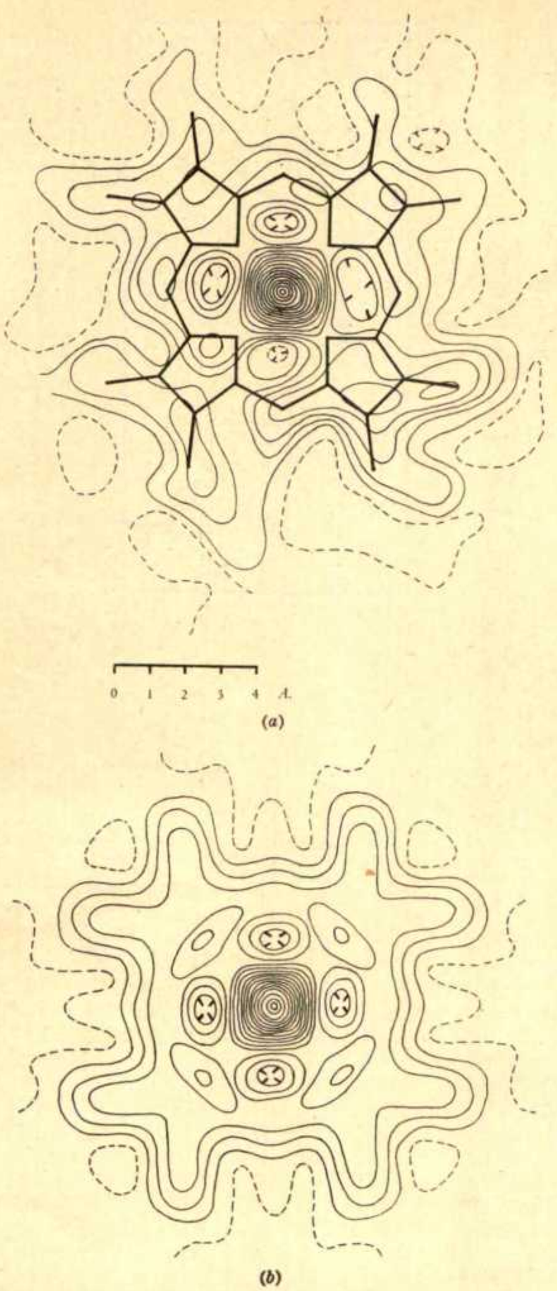

Fig. 2. (a) Observed electron density distribution in the plane of the hæm group, with the atomic arrangement in the group superposed. One contour interval = 0·5 electron/Å^3. (b) Calculated electron density distribution, computed from the known atomic arrangement as described in the text. One contour interval = 0·5 electron/Å^3

examination shows that, in fact, the cylindrical tubes are helices, consisting of a single strand of high density with axial repeat about 5·4 Å. The density in one such helix is shown in Fig. 1*a*. This was obtained by projecting all the density lying within a cylindrical shell of radii 1·6 and 2·3 Å. on to the surface of a cylinder of radius 1·95 Å. and co-axial with the helix; the cylinder was then cut along a line parallel to its axis and unrolled. Superposed on the contours of electron density is the cylindrical projection of an α-helix, with the dimensions given by Pauling and Corey[8]. It will be seen that the observed density follows the configuration of the α-helix with remarkable precision; and it may confidently be asserted that not only this, but also several other lengths of polypeptide chain which have been analysed in the same way, possess the α-helical configuration. It is also found that the side-chains emerge at intervals of 100° around the periphery of the helix, and at axial intervals of 1·5 Å., in conformity with the parameters of the α-helix. Several indirect lines of evidence had led to the conclusion that parts of the polypeptide chain in globular proteins are in the form of α-helixes, and in hæmoglobin Perutz[9] had found traces of an X-ray reflexion characteristic of this configuration; but these results are the first direct proof that α-helices are present and, indeed, enable them to be seen directly for the first time.

The next question is whether the α-helices are left-handed or right-handed; helices of either hand

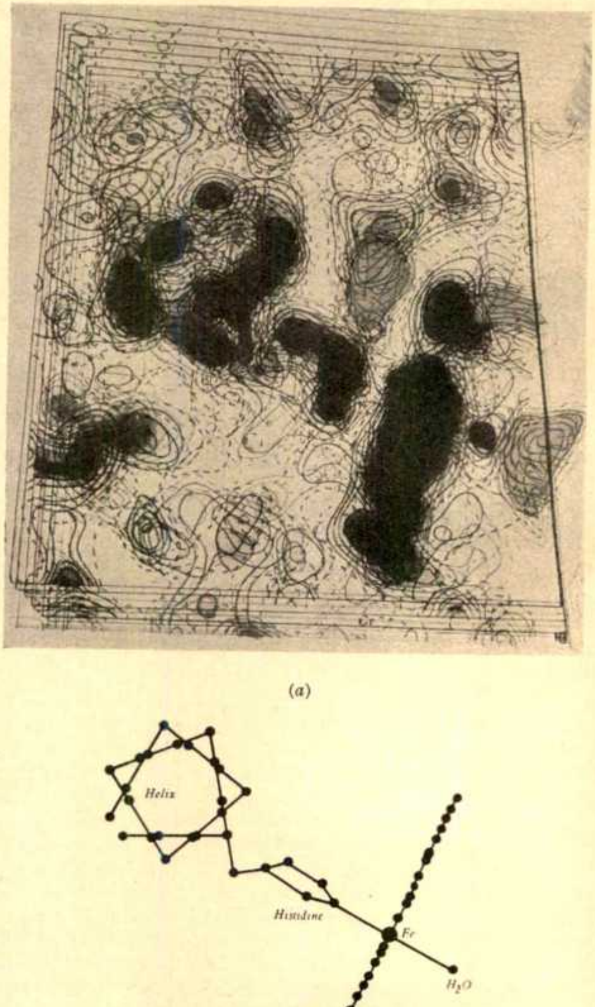

Fig. 3. (a) Photograph of a set of sections normal to the plane of the hæm groups showing, from left to right, a helix in cross-section, the histidine residue nearly edge-on, the hæm group edge-on, and a presumed water molecule. (b) Sketch showing the atomic arrangement in Fig. 3*a*

can be built, and although the right-handed form appears to be marginally the more stable, the difference is not so great as to make it certain that left-handed helices cannot exist. To decide this question, it is necessary to determine the absolute configuration of the Fourier synthesis; this function has no centre or plane of symmetry and might be plotted in two ways, each of which would be the mirror image of the other. The absolute configuration could be settled by making use of the anomalous dispersion of X-rays from the iron atoms or the introduced heavy atoms; we have not in fact made use of this effect, but instead have proceeded in the following way. In a right-handed α-helix composed of L-amino-acids, the first atom of the side-chain (C_β) projects from the main chain in a direction *opposite* to the C—O bonds of the carbonyl groups; in a left-handed helix of L-amino-acids C_β projects in the *same* direction as the carbonyl groups (see Fig. 1*b*). By constructing a second cylindrical projection (not illustrated) of the density near a radius of 3·34 Å., corresponding approximately to the radius at which C_β is found in either case, we found that C_β was systematically on the side of the main chain opposite the oxygen atoms of the carbonyl groups. This shows that the helix must be right-handed, and we were able to plot the Fourier synthesis with the correct absolute configuration by taking account of the known absolute configuration of a L-amino-acid[10]. The molecule was then found to be of the same hand as all the closely similar sub-units in hæmoglobin, the absolute configuration of which was determined by measurements of anomalous dispersion[4]. All the lengths of α-helix in the myoglobin molecule turn out to be right-handed. Finally, it will be clear from Fig. 1 that it is possible to determine by inspection the direction in which the C—O group points, and hence to see which is the terminal carboxyl end of each segment.

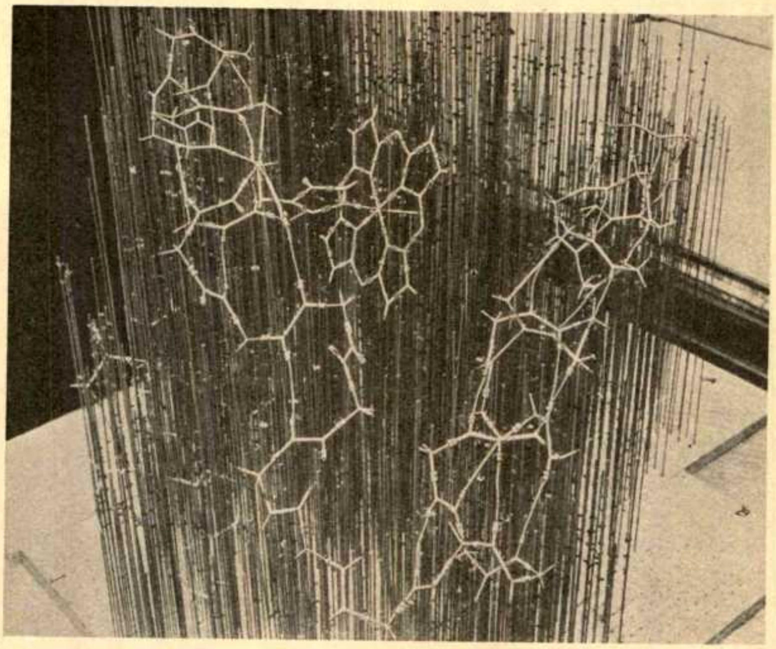

Fig. 4. Photograph of a model of part of the molecule near the hæm group, showing the vertical rods and coloured clips which indicate the electron density at each point of the grid, and atomic models of the hæm group and neighbouring helices. The terminal carboxyl end of the chain is on the extreme left

The α-helices can also be located by building atomic models into the model of the unit cell made with steel rods; this has been done for all the segments of helix in the molecule, and it is found that the total number of amino-acid residues contained in these segments is 100–110, whereas the number of residues contained in the whole molecule is believed to be 153 (Edmundson, A., unpublished results). Thus, 65–72 per cent of the molecule consists of regular right-handed α-helix, made up of about eight segments, each containing between seven and about twenty residues.

When the chain turns a corner, its regular helical configuration is necessarily disrupted. At the present resolution the precise arrangement of the residues at corners is difficult to determine; we have, nevertheless, built plausible models of several corners, though we do not yet claim to have established their configurations with certainty. Most of the corners take up two or three residues, and in addition there is one region (on the extreme right of Fig. 5*a*), consisting of about 13–18 residues, in which the arrangement is irregular (part of it is helical, but probably not α-helical). Further studies will be devoted to elucidating these problems.

No serious attempt has yet been made to identify the side-chains, and indeed it is doubtful whether this can be done systematically at the present resolution, partly because many of them appear to be subject to considerable thermal vibration, partly because there are often interactions between two side-chains on adjacent turns of the same helix or on adjacent helices, and it is difficult to tell where one ends and the other begins. In special cases, however, identification is easy; thus, in several places two helices approach one another closely, and one or more side-chains must for steric reasons be glycine. On the other hand, some side-chains are so long that they can only be arginine or lysine. It remains to be seen how many positive identifications can be made; but it is clear that if the whole amino-acid sequence of the protein were known, it would be possible at this stage to construct a model of the complete structure with fair precision. Unfortunately, this information is not yet available; but in the meantime it may be possible to correlate and check our findings with the partial results of the sequence determination now being undertaken by Mr. A. Edmundson, of the Rockefeller Institute.

The Hæm Group

The identification of a disk of high electron density in the 6-Å. synthesis as the hæm group is confirmed by the 2-Å. synthesis; but the iron atom is now just resolved from the nitrogens of the porphyrin ring (the iron–nitrogen distance is about 1·9 Å.) and the structure of the group as a whole corresponds closely with theoretical expectation. Fig. 2*a* shows a section through the density distribution, cut in the plane of the hæm group; superposed on the section is a model of the hæm group with the dimensions

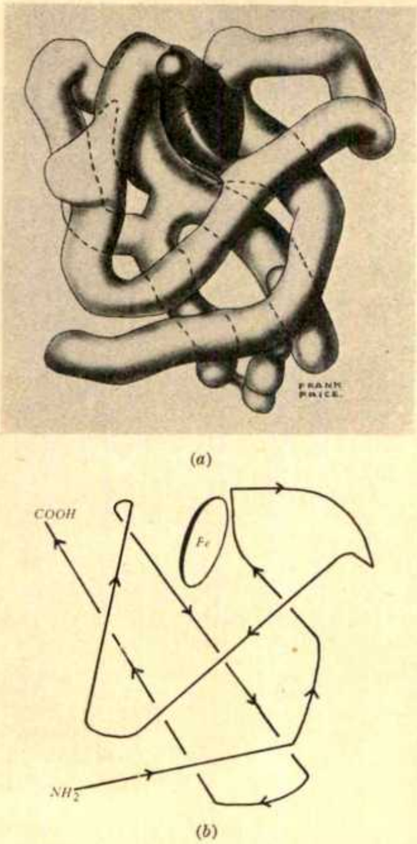

Fig. 5. (a) Drawing of the tertiary structure of myoglobin as deduced from the 6-Å. Fourier synthesis. (Note: the plane of the hæm group is indicated incorrectly in this drawing—see text). (b) The course of the polypeptide chain, deduced from the 2-Å. Fourier synthesis

found by Crute in his recent structure analysis of nickel etioporphyrin[11]. In the model, only the carbon atoms of the methyl groups and the first carbon atoms of the vinyl and propionic acid groups have been indicated; our analysis has not yet proceeded far enough to identify the latter groups. Fig. 2b is a Fourier synthesis made by calculating structure factors for the model structure in a convenient unit cell, applying to these the same temperature factor as that observed in myoglobin, and using them as terms of a Fourier synthesis cut off at 2-Å. spacings. It will be seen that the calculated and observed density distributions agree very closely; furthermore, the observed peak density (8·8 electrons/Å.^{3}) and half-width (1·8 Å.) of the iron atom agree well with the predicted values (8·2 electrons/Å.^{3} peak density, 1·8 Å. half-width). Errors are, of course, inherent in a Fourier synthesis produced from experimental results; the good agreement between the observed and calculated versions of the hæm group, and between the helical polypeptide chain and the α-helix (Fig. 1), indicate that in the present case these errors are fairly small, certainly less than we had anticipated.

In one respect the 6-Å. model now requires correction. Measurements of electron spin resonance[12] had shown that the two hæm groups in the unit cell were tilted out of the *bc* plane through 21° about an axis parallel to *c*, one in one direction and one in the other, but from these measurements one could not decide which direction of tilt was associated with the hæm group of which molecule. In the 6-Å. analysis the wrong choice was made; the new results show that the angle of tilt is indeed very close to 21°, but that it should be in the direction opposite to that shown in earlier models (including Fig. 5a).

Chemical studies of hæmoglobin and myoglobin have suggested that the hæm group is attached to the protein by a bond from the iron atom to a nitrogen atom of a histidine residue, and that the sixth co-ordination position of the iron atom is occupied in met-myoglobin (at *p*H's below 7) by a water molecule. Our results are in conformity with these suggestions. Fig. 3a is a photograph of a series of sections cut through the hæm group normal to its plane. The hæm group is seen edge-on; to its left is the histidine residue, also nearly edge-on, and to the left of that is the helix to which the histidine is attached, seen in cross-section. To the right of the hæm group is a small isolated peak which we take to be the oxygen atom of the water molecule (see Fig. 3b). When this structure is built with atomic models (see Fig. 4), it is found to satisfy all known requirements as to bond-lengths, angles, etc. Thus the iron–oxygen distance is close to 2·1 Å.; that between the iron and one of the histidine nitrogen atoms is 1·9 Å., while the second histidine nitrogen points with its hydrogen directly at a carbonyl group on the helix, presumably forming a hydrogen bond (forked at the carbonyl end); and finally the bonds about the C_α—C_β bond of histidine are almost exactly in the staggered configuration.

General Configuration of the Molecule

In the 2-Å. synthesis the continuity of the polypeptide chain can be followed throughout the molecule; in addition, its direction can be ascertained in each straight segment by examining the direction of the carbonyl groups in the cylindrical projections or by direct model-building. The 'run' of the chain so deduced everywhere agrees with that derived from the 6-Å. synthesis, as well as resolving several ambiguities in that model, and the terminal amino- and carboxyl-ends of the chain can now be identified. The arrangement is shown in Fig. 5 (see also Fig. 5 in the accompanying article by Perutz *et al.*). The overall shape of the molecule is as previously deduced.

Conservative estimates suggest that it may now be possible to locate with some precision at least 43 per cent of all the atoms (excluding hydrogens) in the molecule—namely, those making up the hæm group and the backbone of the regular segments of helix, together with the associated C_β's. We believe that it may be possible, either by straightforward refinement procedures or by heavy-atom methods, to extend the resolution of the synthesis to a point near the limit of the diffraction pattern of sperm-whale myoglobin crystals (about 1·5 Å.), and thus to reveal in any event most of the details of the atomic arrangement of the molecule. Further work is in hand with this end in view.

We wish to thank the Rockefeller Foundation for its generous financial support; the National Science Foundation (U.S.A.) for providing a fellowship for one of us (R. E. D.); to the National Institutes of Health (U.S.A.) for fellowships (R. G. H., R. E. D.); and to the Director and Staff of the Mathematics Laboratory, University of Cambridge, for facilities on the *Edsac* and for their enthusiastic co-operation. We also wish to thank Miss Mary Pinkerton, who was responsible for the organization of the very

extensive programme of data processing, and who helped us in many other ways; a large number of computing assistants, especially Mrs. J. Blows, Mrs. W. Browne, Mrs. V. Cotterill, Mrs. A. Hartley, Miss J. Hughes, Mrs. J. Moss, Mr. P. Mulhall, Mrs. K. Parkes and Miss E. Rowland; Dr. M. G. Rossmann and Dr. E. Alver for making available several of their computer programmes; and Sir Lawrence Bragg for his encouragement at all stages of the work.

DEVELOPMENTS IN GAMMA-RAY OPTICS

By Prof. P. B. MOON, F.R.S.

Physics Department, University of Birmingham

DURING the past decade, several phenomena that had previously been observed with light or with X-rays have been studied with nuclear γ-rays, where the quantum energy is typically 100 keV.–10 MeV. and the wave-length correspondingly short, 10^{-9} to 10^{-11} cm. Some new phenomena, specifically nuclear or specifically high-energy, have been added: but most of the experiments, though often technically more difficult, are extensions of those familiar at lower energies.

An excellent example of such an extension is the curved-crystal γ-ray spectroscopy of γ-rays, achieved with great elegance and precision by DuMond[1] and his collaborators. It will suffice to quote their value for the wave-length of electron–positron annihilation radiation, namely, 24·262 ± 0·0033 mÅ., and to mention that this radiation, when generated within a metal, has been observed to possess a spectral width which reflects the spread of energy of the conduction electrons.

A second example is the observation in the γ-ray region of Rayleigh scattering, a name taken over from visual optics to describe scattering of photons by the electronic structure of an atom without change of the atom's quantum state and therefore without any change of the photon's energy, except the small fraction taken by the recoil of the atom necessary to conserve momentum. This is the 'unmodified line' of X-ray scattering terminology, as opposed to the 'modified line' that arises from Compton scattering. The existence and (if it existed) the origin of elastic scattering at higher energies was a matter of controversy in 1930–33, but it is now clear that Meitner and Kösters observed it[2] and that its origin was electronic, not nuclear. In taking up the study of this scattering process with the wider range of mono-energetic lines provided by artificial radionuclides, Moon[3], Storruste[4] and Wilson[5] were able to verify semi-quantitatively the calculations of Franz[6] regarding its intensity and angular distribution, and many other workers have since made accurate experiments at energies above 1 MeV. where Franz's theory (which is essentially a Debye form factor) must be replaced by the more accurate relativistic treatment of Brown, Peierls and Woodward[7].

Two phenomena not observable in the X-ray region were predicted to be interwoven with the Rayleigh scattering; first, the classically calculable 'Thomson' scattering of photons by the nucleus, which oscillates in the electric field of the incident wave and radiates at the same frequency; secondly, scattering by virtual pair production in the field of the nucleus, which is a specifically quantum phenomenon.

The interest in the nuclear Thomson scattering seems to date from 1950, when it was remarked[8] that it should be coherent with Rayleigh scattering, but the process must surely have been considered long before then; the virtual pair production process was suggested as long ago as 1933 by Delbrück in a note to the paper of Meitner and Kosters[2].

Both processes were difficult to identify because the scattering radiation is of exactly the same frequency as the Rayleigh scattering but, at ordinary γ-ray energies, of much smaller intensity. The Thomson scattering was plausibly identified by the fact that the observed angular distribution of the total elastic scattering agreed much better with theory when this component was added into the calculation; its existence and its interference with the Rayleigh component were positively established by Sood's[8] measurements of the polarization of the elastic scattering at about 1 MeV., at which energy the Rayleigh and nuclear Thomson components have substantially different polarizations. The use of polarization for examining elastic scattering of γ-rays is pleasingly reminiscent of Lord Rayleigh and the blue of the sky.

The characteristic features of the Delbrück process are that its magnitude increases as a high power of the quantum energy and its angular distribution is strongly peaked around 0°. It has at last been unquestionably observed by Moffatt and Stringfellow[9] in Oxford, using 90-MeV. radiation from an electron synchrotron and working at angles of about 0·1°.

Another process of elastic scattering of γ-rays is that associated with the excitation of a nucleus from its ground-state to an excited state followed by the re-emission of a photon. This is the nuclear analogue of the optical resonance radiation so beautifully demonstrated by R. W. Wood in the early years of this century. It was sought experimentally at intervals over twenty years, the difficulty being not that the process is intrinsically weak (its cross-section, like that of any comparable resonant process, can be of the order of $\lambda^2/4\pi$) but that γ-ray lines are so narrow that the loss of energy to nuclear recoil ($h^2\nu^2/2Mc^2$ on emission and equal amount on absorption) destroys the resonance[10].

It was observed ten years ago[10] by the use of a high-speed rotor (not an ultracentrifuge, as it is called by some writers; the correct term is probably 'motor', since it is motion, not specifically rotary motion, and certainly not centrifugal force, that is needed) on which the source of γ-rays was mounted, so that the Doppler effect of bulk motion of the sources brought the emission spectrum into coincidence with the resonance of the scatterer. Both the emission and the absorption lines are broadened far beyond their natural width by the Doppler effect of thermal motion. Experimental results obtained by Davey and Moon[11] demonstrated the essentially thermal shape of the mercury-198 resonance line; its width is less than 1 eV. in 411 keV., which is comparable with the fractional width of the narrowest visible lines.

The phenomenon has been observed with several means of securing partial overlap of absorption and emission lines: by heating the source[12], by using atomic recoil from a preceding beta, gamma or neutrino emission[13–15] or by absorption of the resonance radiation in a second layer of the same material[14]. It has proved valuable for measuring the life-times of nuclear levels in the range 10^{-10} to 10^{-14} sec., and details such as the angular distribution[16] and the plane polarization[17] of the resonance radiation at 90° have been duly verified.

When the excited state decays largely through an intermediate level, the fluorescent radiation can be observed[15]. A particularly interesting application of the neutrino-recoil method was made by Goldhaber, Grodzins and Sunyar[22], who showed that in special circumstances the resonance radiation can be circularly polarized; they used this fact to determine the spin polarization (helicity) of the neutrino.

One is not restricted to γ-rays from radioactive sources: nuclear reactions, with the forward momentum of the excited nucleus as the overlapping agent, have been used both in scattering[18] and in absorption[19,20] experiments, and bremsstrahlung has been used to excite a particularly broad level[21].

A major development was reported in 1958 by Mössbauer in Munich[23]. He showed, using the 121-keV. line of iridium-191, that in crystals at low temperatures appreciable fractions of the emission and resonant absorption processes for low-energy γ-rays occur without nuclear recoil and indeed with no loss of energy between the γ-ray and the crystal other than that due to the recoil of the crystal as a whole; for these fractions, the line has only its natural width and may be brought out of resonance by relative motion of source and absorber of the order of 1 cm./sec. as compared with the order of 10^4 cm./sec. required to sweep the thermally broadened components over one another. The Mössbauer line sits as an extraordinarily tall and narrow spike on top of the thermal profile, at the same position for both emission and absorption. The cross-section for the Mössbauer effect is a sizable fraction of its ideal value ($\sim \lambda^2/4\pi$) and, even at 100 keV., can be appreciable in comparison not merely with the Rayleigh but also with the Compton and photoelectric cross-sections.

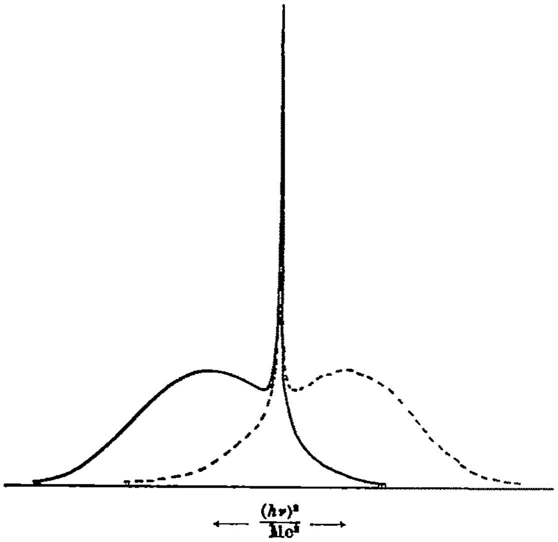

Fig. 1. Emission line profile (full line) and absorption line profile (broken line). The narrow line is present only with low γ-ray energies and cold crystals, when it may be $\sim 10^6$ times as high as the surrounding thermally broadened line and contain a large fraction of the total area

It is a curious reflexion on the journal-reading habits of physicists that Mössbauer's discovery was not generally known for a year after its publication; during the past few months, workers in many laboratories have realized its exciting possibilities. These are of two classes: its use to investigate the response of crystals to the offer of amounts of energy comparable with $k\theta$, where k is Boltzmann's constant and θ the Debye temperature, and the much more varied class of experiments that exploit the extreme narrowness of the line.

The effect has recently been observed in several laboratories with the 14 keV. line in iron-57, which has a width of the order of 10^{-8} eV.—one part in 10^{12} of its energy. It is, in fact, extremely easy to demonstrate, requiring only a thin source of cyclotron-irradiated iron, an absorber of ordinary iron, and a proportional counter or scintillation counter. Even at room temperature, changes of counting rate of the order of 30 per cent are observed when the source is oscillated at a speed of less than a millimetre per sec.

Perhaps the most exciting application of the Mössbauer effect is to observe the effect of gravitational fall on the energy of the photons (the 'terrestrial red-shift experiment') which appears measurable over a vertical distance of less than 100 m.: such experiments are understood to be in progress in the United States, England (Harwell and Manchester)[24] and the U.S.S.R. Another interesting experiment, being tried at Harwell and Birmingham, relates to special rather than general relativity; the source is mounted at the centre of a spinning rotor, the resonant absorber at the edge so that, though the distance between them does not change, the photons meet an absorber travelling exactly at right angles to their direction of flight: a second-order Doppler effect ($\frac{1}{2}v^2/c^2$) should be observable.

Mössbauer lines will have structures attributable to the interaction of the crystal's intrinsic magnetic or electric field with the magnetic dipole or electric quadrupole moments of the ground and excited states of the nucleus; Pound and Rebka[24] have already observed the splitting of the iron-57 line in the intrinsic magnetic field of iron. This is distinct from, and much narrower than, the structures due to the excitation of phonons in the crystal which, as Mössbauer pointed out, are analogous to effects observed in the scattering of very slow neutrons in crystals. In favourable instances the nuclear Zeeman effect should be observable.

One may imagine, too, searches for effects of electric or magnetic fields upon any small electric or magnetic moments that may be possessed by free photons, and one can see interesting problems concerning the limitations to the possible narrowness of Mossbauer lines from transitions still longer-lived than the 10^{-7} sec. iron-57. Are these limits due to fluctuations in crystal fields, to the finite size of the crystal (or of whatever part of it may act as a unit in declining to accept the proferred recoil energy) or to other causes? If the relative motion of the source and the absorber is at a frequency high compared with the inverse lifetime of the excited state, will the process recognize or ignore this motion?

The recoilless absorption process should be accompanied by sharply resonant scattering, weakened by the strong internal conversion of low-energy gamma transitions. In experiments at Birmingham, with gold-197, it appears just observable. This scattering should be coherent with the Rayleigh component and, in favourable circumstances, should show the lattice interference patterns familiar in X-ray work from which not only the positions of the resonantly scattering nuclei but also the phase of scattering should be measurable.

Thus, after a long period of little progress, γ-ray optics now offers a range of phenomena comparable with those known in the fields of light and of X-rays, and, though admittedly in rather special circumstances, a far superior resolving power.

OBITUARIES

Prof. P. Lebeau

PAUL LEBEAU, professor of pharmaceutical chemistry, Paris, and member of the Paris Academy of Sciences, died on November 18, having nearly reached the age of ninety-one.

Lebeau began his career in chemistry as a student at the École de Physique et de Chimie, Paris, and his outstanding qualities were immediately appreciated by Prof. Étard. His early publications attracted the attention of H. Moissan, and when the latter was appointed to the chair of chemistry in the Faculté des Sciences at Paris, Lebeau was made director of his laboratory. His researches in inorganic chemistry, particularly with regard to fluorspar and fluorine, led to the degree of D.Sc. in 1898. During this period, he was also studying to become a pharmacist, and he achieved this object in 1899.

Lebeau was appointed to the chair of toxicology in 1908, which position he held until 1918. He deliberately orientated this subject towards industrial hygiene and became intensely interested in its medico-legal aspects. As a result, his services during the First World War were of outstanding merit, and in 1918 he succeeded Prof. Charles Moureu in the Berthelot chair in the Collège de France. His great energy and outstanding ability were then directed towards the subject of pharmaceutical chemistry, and his efforts met with similar international recognition as they had already done in the realm of toxicology. His treatise on pharmaceutical chemistry has passed through many editions and is accepted as a standard work on this subject.

As president of the Commission des Hautes Températures of the Centre National de la Recherche Scientifique he was largely responsible for the outstanding success of this body, which resulted in the publication in 1924 of an important book entitled "Fours Électriques et Chimie". This work has attained international recognition.

Not unnaturally, the services of a scientist of such outstanding merit were in great demand, particularly in connexion with government and international committees. These services were given without restraint, and Lebeau made outstanding contributions during his connexion with the Commission des Études Chimique de Guerre, the Conseil d'Administration du Centre National de la Recherche Scientifique, the Commission Internationale des Poids Atomique, and the Société Chimique de France.

Prof. Lebeau's long life covered the period when the science of chemistry was expanding rapidly, a period which was characterized by the introduction of many new chemical concepts. He played his part in this new thinking and can be regarded as one of the architects of modern pharmaceutical chemistry. His career and devotion to the science should be a stimulant to all future students of chemistry.

W. H. LINNELL

Mr. P. R. Coursey

MR. PHILIP RAY COURSEY, of the Dubilier Condenser Co., Ltd., died on January 3. Mr. Coursey, who was born in 1892, was educated at University College, London, and became assistant to Sir Ambrose Fleming at the College. During the First World War he was Admiralty inspector of wireless telegraphy in H.M. Auxiliary Patrol, and in 1919 became technical research assistant at H.M. Signals School. During

1920–23 he was on the editorial staff of the *Radio Review* and the *Wireless World*, to the second of which journals he was a frequent contributor. During this period he was an active and enthusiastic member of the Wireless Society of London (later, the Radio Society of Great Britain); and he was responsible for organizing the British amateurs who in 1921 co-operated in the tests conducted by the American Radio Relay League for establishing radio communication between the United States and Britain. Mr. Coursey was also an active experimenter in the early development of wireless telephony, and was the author of several books on this and allied subjects. He became chief engineer of the Dubilier Condenser Co., Ltd., in 1923, a position which he held until 1931, when he was appointed technical director of the Company; he retained that position with distinction until his retirement in 1957, when he was appointed technical consultant in addition to retaining his directorship.

Mr. Coursey was the originator of many important developments and held numerous patents. His extensive knowledge and experience have been a valuable contribution to the industries with which he was connected. He also took a prominent part in and made valuable contributions to the deliberations of the electrical and telecommunications industries both on British and international committees.

NEWS and VIEWS

Theoretical Physics at St. Andrews :
Prof. R. B. Dingle

Dr. Robert Balson Dingle, reader in theoretical physics in the University of Western Australia, has been appointed as the first occupant of the new chair of theoretical physics in St. Salvator's College of the University of St. Andrews. After a notable undergraduate career as Bournemouth Borough Scholar and major scholar at St. John's College, Cambridge, during which he held the Wright Prize twice and also the Hughes and Hockin Prizes, and at the end of which in 1946 he confused his Tripos examiners by, in effect, dismissing their questions and setting and answering his own, he found a corner in the Royal Society Mond Laboratory and began his research career, shortly thereafter being appointed to a fellowship at his College. Almost immediately, he began to publish, and a steady stream of valuable papers has continued since, uninterrupted by a series of moves of increasing geographical amplitude, first to Bristol, then Delft, then Ottawa, and then Nedlands in Western Australia.

Dr. Dingle's publications have covered three main fields and a few small ones. First, chronologically, came a series of elegant papers clarifying the hydrodynamics of liquid helium II, and in particular, second sound. This was followed by a series on collective electron effects in metals, in which diamagnetic or cyclotron resonance was predicted. This series also contained several important contributions to the understanding of the complicated oscillatory magnetic phenomena in metals known as the de Haas–van Alphen effect, and the removal of the apparent discrepancy between observation and theory of optical reflectivity in metals by an extension and correction of the Reuter–Sondheimer theory. The most recent series of papers is more mathematical and is concerned with the evaluation of integrals used in mathematical physics. In addition to these three main streams, he has also made useful contributions on semi-conductors and on quantum and statistical mechanics.

Pharmacology in London :
Prof. G. V. R. Born

Dr. G. V. R. Born, recently appointed to the Vandervell chair of pharmacology at the Institute of Basic Medical Sciences in the University of London, took his M.B. and Ch.B. at Edinburgh in 1943 and his D.Phil.(Oxon) in 1951. After his return from service as army pathologist in the Far East, he took up research in the rapidly developing new field of biochemical pharmacology. While on the staff of the Medical Research Council's Toxicology Research Unit he became interested in metabolic inhibitors, and, on returning to the Nuffield Institute for Medical Research at Oxford in 1953, he studied the actions of these inhibitors on smooth muscle. His main field of work has been on the pharmacologically active amines, and this led him to study the blood platelets by biochemical and pharmacological methods. A most notable contribution was the discovery of large amounts of adenosine triphosphate in platelets. The role of this substance in the uptake and storage of 5-hydroxytryptamine by platelets and its fate during clotting are now being explored. Dr. Born has also taken an active part in the teaching at Oxford, both in the Departments of Pharmacology and Pathology, and as a medical tutor at St. Peter's Hall. He has travelled widely and is well known to his scientific colleagues on both sides of the Atlantic.

College of Advanced Technology, Birmingham :
Dr. T. Lupton

Dr. T. Lupton has been appointed head of the Department of Industrial Administration of the College of Advanced Technology, Birmingham, as from April 1. At present senior lecturer in industrial sociology in the University of Manchester, Dr. Lupton began his career as an apprentice marine engineer, and later became an engineering draughtsman. He afterwards gained a diploma in economics and political science at Ruskin College, Oxford, proceeded to an honours degree in economics at Oriel College, Oxford, and was awarded the degree of Ph.D. at Manchester in 1959. Dr. Lupton has carried out a number of investigations on the relationship between occupation and social status, and recently the Department of Scientific and Industrial Research granted him £29,000 for a five-year research project on "Social Factors affecting Workshop Behaviour"; he will be continuing this work at Birmingham with the aid of Research Fellows and assistants.

National Institute of Agricultural Botany :
Mr. G. W. G. Briggs

Mr. G. W. G. Briggs has been appointed assistant director of the National Institute of Agricultural Botany. Since 1948 he has been head of the Seed Production Branch of the Institute, where he was responsible for the development of field approval and certification schemes for the improvement of cereal, herbage and vegetable seeds. The post of assistant director was created following the resignation of Mr. A. Sandison, who has been deputy director of the Institute during the past seven years.

Institution of Electrical Engineers: New Honorary Members

THE Council of the Institution of Electrical Engineers has elected the following to honorary membership: Colonel B. H. Leeson, recently director of the British Electrical and Allied Manufacturers' Association, in recognition of his extensive contributions to the application of electrical science and engineering in the manufacture of electrical plant and equipment, to the development of co-operative effort within the electrical industry and to the training of electrical engineers, and of the services he has rendered to the Institution during nearly half a century; and Dr. Richard L. Hearn, for his notable contributions in the development of electricity generation and its supply for the benefit and use of mankind, particularly in Canada, and for the part he has played in international co-operation in this field. Dr. Hearn was elected under the provisions of the rule whereby the Council is empowered to elect, once in every three years, an additional honorary member who is not at the time of his election a member of any class of the Institution.

Faraday Medal

THE thirty-eighth award of the Faraday Medal of the Institution has been made to Sir George Thomson, president of the British Association, in recognition of his outstanding contribution to the advancement of electrical science, of the leadership in research which he has given to others in this field, and of his inspiring services to education in science and technology. This Medal is awarded not more frequently than once a year, either for notable scientific or industrial achievement in electrical engineering or for conspicuous service rendered to the advancement of electrical science, without restriction as regards nationality, country of residence, or membership of the Institution.

Youth Services in Great Britain

IN the House of Commons on February 3, the Minister of Education, Sir David Eccles, announced that the Government accepted in principle all the main recommendations for Government action of the report of the Committee appointed in November 1958 under the chairmanship of Lady Albemarle to review the contribution which the youth service in England and Wales could make in assisting young people to play their part in the community. The necessary discussions between the Ministry of Education, the local education authorities and the voluntary youth organizations, with the view of taking precise decisions how to act on the Albemarle recommendations, will take place urgently. The Government has decided that deficiencies in voluntary and paid workers, in buildings and facilities for sport, in money and enthusiasm, must be made good, though everything cannot be done at once, and the will to succeed must come from the local areas at least as much as from the centre. The Government will finance by Exchequer grant most of the recommended expansion in training facilities from 700 to 1,300 full-time youth leaders by 1966, and Sir David hopes an emergency training college will be open by January 1, 1961. He proposes to ask interested parties to examine with him the execution of the recommendation regarding salaries and opportunities for transfer to other careers. Grants for starting buildings by the local authorities and voluntary organizations in the next two years will be authorized up to £2 million, and grants to voluntary projects will be increased. Grants will be increased for headquarters expenditure of voluntary organizations for approved experiments in attracting young people not now using the youth service. Sir David said that, to begin with, he proposes himself to take the chair of the recommended Youth Service Development Council.

Sir David undertook to consider a suggestion that the House should discuss the Albemarle and the Crowther Reports together, and said that the Government proposes to accept the recommendation that the age-range of the youth service should be 14–20 years. A corresponding statement was made on the same day by the Minister for Science, Lord Hailsham, in the House of Lords.

Gasification of Coal and Oil

REPLYING to a question in the House of Commons on February 1, the Minister of Power, Mr. R. Wood, said the Gas Council is spending £120,000 this year on research into coal gasification, and the National Coal Board and the Central Electricity Generating Board £680,000 and £130,000, respectively, on coal utilization. The Gas Council is spending about £230,000 on research into the gasification of oil under a programme intended to contribute also to the improvement of the economics of coal gasification, and another £240,000 on research into problems of gas purification and the treatment of by-products.

Trans-Pacific Telephone Calls

THE United Kingdom Government has accepted the report of the Pacific Cable Conference, which was held in Sydney during September–October 1959, and in which Government representatives from Canada, Australia, New Zealand and the United Kingdom participated. Cable and Wireless, Ltd., will act for the United Kingdom Government in the construction, maintenance and financing of the cable. The total estimated cost is £26·3 million, of which the United Kingdom share is £8·3 million. The cable will be more than 8,000 nautical miles long and will include more than three hundred under-sea amplifiers. In places, cable and amplifier will be laid to a depth of almost four miles. The project is to be undertaken by a joint Commonwealth Management Committee. The Committee will be under the leadership of Mr. R. J. Halsey, director of research of the United Kingdom Post Office. A light-weight cable will be used with rigid repeaters developed in the United Kingdom and being used in Cantat, the cable between the United Kingdom and Canada. The Trans-Pacific Cable will have a capacity for at least eighty simultaneous conversations. Any one of the telephone circuits can be used to provide twenty-four telegraph channels.

National Central Library

THE forty-third annual report of the Executive Committee of the National Central Library, covering the year ended February 28, 1959, records that although the requests for loans continue to become more specialized and inaccessible in nature, the proportion of applications handled successfully continues to rise and is now 76 per cent (National Central

Library. 43rd Annual Report of the Executive Committee for the year ending February 28, 1959. Pp. 20. London: National Central Library, 1959). Attention has been given to the problem of increasing the speed with which books can be obtained, and here delays are chiefly due to the failure of some libraries to deal promptly with the requests of the National Central Library. The Executive Committee appeals strongly to all co-operating libraries and regional bureaux to help by dealing with requests with the minimum of delay. Total applications again decreased, from 79,971 in 1957–58 to 77,004, and of the 76,048 volumes issued from or through the Library (including renewals), 32,666 were to or from public libraries; 12,202 to or from university libraries; special outlier libraries, 8,704; overseas libraries, 3,077; Government departments, 2,528; industrial and research organizations, 3,497; and adult classes, 11,286. Overseas libraries lent 1,804 volumes and borrowed 2,488 volumes, and 240 and 432 further requests, respectively, were satisfied by photographic reproductions. The outlier libraries, now numbering 281, lent 14,525 volumes, and other special libraries a further 2,527 volumes. Regional co-operation covered 163,842 loans within systems, and 22,099 outside systems and the university libraries supplied 24,390 books and borrowed 12,202. The arrears in the incorporation of entries for the union catalogues increased and the problem has been specially examined. There was a marked increase in the work of the British National Book Centre.

Teacher Training in Britain

More than 31,000 men and women are now training to become teachers, an increase of nearly a third compared with the 24,500 under training five years ago. The number entering training colleges this autumn had also increased by a third—16,000 compared with 12,000 in 1955–56. Standards are rising, most of the students now having more than the minimum academic qualifications for entry. The training colleges will thus be sending a record number of trained teachers into the schools in 1961. This will help to tide over the so-called 'year of intermission' in 1962, when there will be fewer newly trained teachers entering the schools as a result of the lengthening of the training course from two to three years. Expansion of the teacher training colleges by nearly two-thirds is now under way; many of the 130 training colleges are to be extended and new colleges built.

Recruitment for next year's intake is already starting, and the Ministry of Education has issued a revised booklet, "Becoming a Teacher", to help young people who want to teach in primary or secondary schools. The booklet describes the work the teachers do, the schools in which they teach, the qualifications they require and the training they undertake. It includes information about the training grants available and the salaries paid to teachers. The booklet can be obtained free from any local authority or from the Ministry of Education, Curzon Street, London, W.1.

Rubber Industry Display at the Science Museum

A permanent display representative of both producing and manufacturing sides of the British rubber industry has been presented to the Science Museum, London. It occupies three large show-cases in the industrial chemistry gallery, and illustrates the molecular structure of natural and synthetic rubbers; their production, compounding, and processing; the great variety of products thus obtained, and the vital part they play in modern life. The display has been devised and organized by the Federation of British Rubber and Allied Manufacturers and made possible by the generosity of British manufacturers of rubber products; makers of synthetic rubbers, compounding chemicals, processing machinery and components; the Natural Rubber Development Board, representing producers of natural rubber; and the National College of Rubber Technology.

National Museum, Bloemfontein

The annual report of the National Museum at Bloemfontein for the year ended March 1959 records the installation of a model of a gold mine and a dioramic display of a Bushman's cave showing rock paintings, stone implements and two modelled figures of men, one in the act of painting against the rock wall, while the other is making stone implements. In contrast with other museums, it was found that an admission charge curtailed severely the number of visitors, and after an experimental period of six months the charge was withdrawn. Much research work by the staff is in progress or has been completed. This includes studies on fossil hippopotami, engraved Bushmen sticks and Karoo vertebrate fossils.

Collecting Fossils, Minerals and Rocks

The seventh edition of "Instructions for Collectors", No. 11, published by the British Museum (Natural History) at 1*s*., follows the usual lines of this well-known and excellent booklet. It will be found to be of use to all types of collectors as, in addition to very elementary instructions, details are given of preparations which have only recently been discovered. The new materials mentioned have in all cases been tested extensively and may be used with confidence.

Marconi International Award

The establishment of an annual award in memory of Guglielmo Marconi is announced by Permindex, the World Trade Centre in Rome. This award will be made to the person making the greatest contribution to the development of Marconi's discoveries. Recipients will be chosen by a committee composed of important international personalities, a member of the Marconi family and representatives of Permindex. This announcement followed the dedication of the Marconi obelisk, to be known as the Marconi Antenna, in the Piazza Italia around which are grouped the four majestic buildings shortly to be occupied by Permindex. To celebrate the occasion the Square itself was renamed Piazza Guglielmo Marconi. The prize consists of a small reproduction in gold of the obelisk. Further information can be obtained from Industrial Trade Fairs, Ltd., Drury House, Russell Street, Drury Lane, London, W.C.2.

Ramsay Memorial Fellowships in Chemistry

The Trustees of the Ramsay Memorial Fellowships Trust will consider in June applications for two fellowships for advanced students of chemistry. One of the fellowships will be limited to candidates educated in Glasgow, who can apply to be considered for either fellowship. The value of each fellowship will be £600 per annum, to which may be added a grant for expenses of research not exceeding £100 per annum. The fellowships will normally be tenable for two years. Further information can be obtained from the Joint Honorary Secretaries, Ramsay Memorial Fellowships Trust, University College London, Gower Street, London, W.C.1. Completed application forms must be received not later than April 11, 1960.

Lady Tata Research Scholarships and Fellowships

The Trustees of the Lady Tata Memorial Trust invite applications for grants, scholarships and fellowships for research on diseases of the blood, with special reference to leukæmia, in the academic year beginning on October 1. In view of the affinity between leukæmia and other forms of neoplastic disease, candidates with programmes of research on any aspect of malignant disease which may throw light on problems of leukæmia will be eligible for consideration. Further information can be obtained from the Secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, Chester Beatty Research Institute, Fulham Road, London, S.W.3. Applications must be submitted before March 31, 1960.

Lectures at the Imperial College, London

The nine inaugural lectures delivered at the Imperial College of Science and Technology during 1956–57 and 1957–58 have now been issued as a bound volume. They comprise those of Prof. B. G. Peters on "Parasitology at Imperial College"; Prof. J. G. Ball on "Metallurgy—Art, Technology, Science"; Prof. W. K. Hayman on "Pure Mathematics at a Technological University"; Prof. Abdus Salam, "Elementary Particles"; Prof. P. V. Danckwerts, "Chemical Engineering in a University"; Prof. D. H. R. Barton, "Some Modern Trends in Organic Chemistry"; Prof. C. C. Butler, "Ultra-High Energy Nuclear Physics"; Prof. F. D. Richardson, "The Changing World of the Extraction Metallurgist"; and Prof. J. M. Kay on "The Nuclear Power Programme and its Impact on Engineering Education" (pp. ii+134+24 plates. London: Imperial College of Science and Technology, 1959).

University News: Birmingham

The University of Birmingham and the University College of Rhodesia and Nyasaland have agreed that when a Medical School is established in the University College at Salisbury, Southern Rhodesia, this School will initially be an affiliated institution of the University of Birmingham. This will mean that, for the period of affiliation, students in the Medical School of the University College will be prepared for degrees in medicine of the University of Birmingham.

The following lecturers have been appointed: J. C. Maltbaek (chemistry); Dr. D. S. Urch (chemistry); G. C.-Y. Hu (highway and traffic engineering); Dr. C. G. Wall (chemical engineering); G. H. J. Bennett (industrial metallurgy); R. S. J. Good (mechanical engineering).

Cambridge

Dr. Kenneth McQuillen, University lecturer in biochemistry, has been appointed College lecturer in biochemistry in Churchill College as from October 1961.

Durham

The University of Durham has received a grant from the University Grants Committee to enable it to place orders for nearly £40,000 worth of additional equipment for the University Computing Laboratory at 1 Kensington Terrace, Newcastle upon Tyne 2. At present, the Laboratory is equipped with a Ferranti Pegasus electronic digital computer, and this installation is to be enlarged by the addition of magnetic tape equipment and of a fast output punch.

London

Dr. R. G. Lipsey has been appointed to the University readership in economics tenable at the London School of Economics and Political Science. The title of reader in economics in the University of London has been conferred on Dr. K. J. Lancaster in respect of his post at the London School of Economics and Political Science.

Announcements

The Messel Medal, the senior award of the Society of Chemical Industry, which is awarded every two years in gold, will be presented to Viscount Chandos in Bristol on July 6 during the annual meeting of the Society. The Medal is awarded for meritorious distinction in science, literature, industry or public affairs.

Prof. E. J. Wayne, regius professor of practice of medicine in the University of Glasgow, has been appointed chairman of the Clinical Research Board, in succession to Sir Geoffrey Jefferson.

Dr. David K. Detweiler, associate professor of veterinary pharmacology in the University of Pennsylvania, has been awarded a grant of 1,100,000 dollars over a period of ten years from the National Heart Institute of the National Institutes of Health, for research and training in comparative cardiovascular studies.

The International Society of Tropical Ecology, with its headquarters at Allahabad, India, was inaugurated by His Excellency the Governor of Bombay on January 5. The following officers were elected for 1960–61: *President*, Dr. J. C. Sen Gupta (Calcutta); *Vice-presidents*, Dr. F. R. Fosberg (Washington), Dr. C. G. G. J. Van Steenis (Holland); *Treasurer*, Dr. R. Misra; *General Secretary*, Dr. G. S. Puri.

An international symposium on "Inhaled Particles and Vapours", organized by the British Occupational Hygiene Society, will be held in Oxford during March 29–April 1. Further information can be obtained from Dr. J. S. McLintock, Medical Service, National Coal Board, Hobart House, London, S.W.1.

A symposium on "Inorganic Chemistry" will be held in the Wallberg Building, Department of Chemistry, University of Toronto, on April 8. Further information can be obtained from Dr. A. D. Allen, Department of Chemistry, University of Toronto, Toronto 5.

A symposium on "Continuous Culture of Microorganisms" will be held during March 31–April 1 at University College, London, under the auspices of the Microbiology Group of the Society of Chemical Industry. Further information can be obtained from the Assistant Secretary of the Society, at 14 Belgrave Square, London, S.W.1.

In the review of the book, "Mathematical Methods of Operations Research", by T. L. Saaty, published in *Nature* of December 5, 1959, p. 1763, it was stated that a printing error occurred on p. 340. Mr. R. Syski, of Hivac, Ltd., South Ruislip, Middlesex, has pointed out that this is not the case, and Prof. L. S. Goddard agrees, adding that the formula is repeated incorrectly on p. 346, where the exponent of μ/λ in the second term is given as $i + n - 1$, whereas the correct exponent is $i - n + 1$.

THE NATIONAL MUSEUM OF WALES

DEPARTMENT OF INDUSTRY

A DEPARTMENT of Industry was founded in the National Museum of Wales, Cardiff, in 1958, and its gallery was opened to the public last December.

The purpose of the Department is to illustrate not only the history and development of the older Welsh industries that were founded upon Welsh raw materials or upon techniques evolved or developed in Wales but also the application of science and research to the industries more recently introduced. In presenting an objective record of technical progress an attempt will also be made to show something of its impact upon human life.

The exhibits are displayed in fixed cases of shop-window type and in standard museum cases. For the present, there is a preponderance of those dealing with the iron and steel industry in Wales; in some exhibits it is looked at from the historical point of view alone, whereas in others the contrast between old and new methods is brought out by combining models of obsolete plant and photographs of modern processes.

The first of the iron-making exhibits contains a model of an anthracite blast-furnace used in the Gwendraeth Valley about 1850, and one of a blast furnace with a stove for heating the air before its injection into the furnace. The latter was associated with the successful attempts of John Budd in adding pre-heating chambers to some anthracite-burning furnaces at Ystalyfera in the Swansea Valley in 1844. Like other contemporary blast furnaces, those at Ystalyfera were constructed of massive masonry enclosing and supporting the fire-brick chambers in which the reactions took place. A further typical example of the construction adopted in South Wales before 1850 is depicted in a model of a blast furnace at the Pen-y-Darren Ironworks. Included in the model is a small pipe stove, consisting of nine semi-circular cast-iron pipes placed in parallel in a chamber heated by a coal fire, by which some of the blast was heated. Coupled with this model is one of a blowing engine used at the works for supplying air to blast furnaces. The type of blast furnace erected at Cardiff between 1888 and 1895 is represented by a half-section model. These furnaces were hand charged until 1927.

Obsolete steel-making plant is illustrated by a model of an open-hearth steel furnace of a type used in South Wales from 1890 until 1900, and included in the same exhibit is a sectional model of a Siemens' gas-producer, formerly the property of Sir C. W. Siemens, representing the modified type of gas-producer which he devised for use with the open hearth process perfected by him in 1867. In an exhibit on steel-making by the Bessemer process, there is a sectional model of a Bessemer converter of 1856.

In 1898 the works engineer at Dowlais Works designed and patented an ingot-stripping machine. Previously the cast-iron moulds had been stripped from steel ingots by hydraulic and steam cranes working alongside the sunken teeming pits. The new stripping machine, hydraulically driven, made it possible for ingots to be cast on bogies and then taken to the soaking pits some distance from the steel-making plant. A model of this machine is on view, and there is also a model of the original engine used at the same works for driving the roughing rolls of the rail-mill.

The hand processes of making tinplates in works dismantled during recent years are illustrated in an exhibit containing tools, photographs and samples of plates in the various stages of rolling from the original tin bar to the finished pack of eights.

At one end of the gallery there is a small transport section showing models of nineteenth-century sailing ships, illustrating the transition from sail to steam, and of early twentieth century cargo steamers under Welsh ownership. There is a model of the first Garratt articulated locomotive built for use in Great Britain, which operated at the Hafod Copper Works, Swansea, and one of a Taff Vale Railway engine and tender of 1867. A working model of a high-pressure steam engine designed by Richard Trevithick is also included; it is of a type installed at iron-works at Pen-y-Darren, Hirwaun and Tredegar at the beginning of the nineteenth century. A small panel of photographs alongside this model illustrates parts of the remains of the tram-road from Merthyr to Abercynon along which the Trevithick locomotive travelled in 1804.

One of the fixed cases contains a model of a rotary cement kiln. This will be supplemented by an exhibit adjacent to it which will include specimens of the raw materials used in the making of cement, of the product at various stages of manufacture, and of photographs of quarries and parts of the plant involved. An exhibit of Welsh exposed-aggregate slabs is also planned. A collection of tools, photographs and drawings illustrates the preparation of roofing slates in North Wales, and there is an exhibit devoted to the history and development of the miner's safety lamp.

The rayon industry is represented in an exhibit illustrating the manufacture of rayon staple and box spinning textile yarn at a factory in North Wales. An exhibit dealing with the nylon industry is being planned, and it is hoped to have another featuring the nickel industry.

Some original machines—a beam engine for pumping water from pits, a water-balance pit-head gear used to raise coal, and a set of rolls and a shear-table from an old-type tinplate works—are installed in the grounds of the Museum.

The gallery as it now stands indicates the field which the Department of Industry is intended to cover. It will be added to as rapidly as circumstances permit; but full use of models and original objects now in reserve cannot be made, nor can the full illustration of the special industries of Wales be achieved, within the confines of the present gallery. Much of this work will have to await the hoped-for addition to the Museum of a west wing.

WATER RELATIONSHIPS OF PLANTS IN ARID AND SEMI-ARID CONDITIONS

THE part played by Unesco in stimulating interest in the problems of the drier regions of the surface of the Earth is widely recognized. Its excellent series of symposia, covering hydrology, utilization of saline water, plant ecology, human and animal ecology, wind and solar energy, and micrometeorology, has done much to crystallize our current concepts of water as an ecological factor and particularly to emphasize the physical background in which it operates. These discussions were extended to the level of the individual plant at a symposium organized in Madrid during September 1959.

Considered as a whole, the two published volumes of the Canberra symposium on micrometeorology and the two volumes of the Madrid symposium, which have yet to appear, provide not only one of the best modern treatments of plant–water relations but also illustrate clearly the way in which plant ecology is casting its traditional shackles and emerging as an active experimental discipline. The Madrid symposium, although leavened with a few soil physicists and plant physiologists, was numerically dominated by plant ecologists. Among these were included representatives of the three modern categories: (i) the 'chroniclers', whose penchant for description and cartography readily translates suggestions into irrefutable dogma and leads to the creation of beautiful but often meaningless maps—multivariate analysis apparently does not yet qualify for an expense account; (ii) the 'partialists', whose methods have not advanced beyond the era of Livingston and Maximov, and whose thought is restricted to the confines of the plant; and (iii) the 'totalists', whose concern is with the entire soil–plant–atmosphere system. It is no accident that the modern approach to experimental ecology represented by the third category should have developed within the applied science of agriculture but simply reflects the stimulus arising from close association between people investigating detailed aspects of different parts of the same system. One of the finest examples of an ecological investigation is that reported at Madrid by R. O. Slatyer on the water relations of two natural communities in Australia. Here, soil physicists, plant physiologists and micrometeorologists are working together and each has a full appreciation of the complete system.

It is also no accident that this approach should emerge first with the study of water because the responses of the plant to water are less complex than to other ecological factors such as light or temperature. Knowledge of the control of the water supply has now advanced to the stage of complete quantitative description, although the values of some parameters are far from exact. Those which are least perfectly known include moisture-release curves, surface roughness, stomatal conductance and the variations in extent of the root-zone with time, species and environment. Several contributors discussed these. The location and sizes of the resistances in the plant to liquid flow are uncertain, although it is now clear that plants may experience an adverse deficit of water in the leaves with the soil water at 'field capacity' when the potential transpiration exceeds ~ 4–5 mm./day. In order to evaluate this and other problems intelligently and to remove general confusion, the status of water in all parts of the soil–plant–atmosphere system must be expressed in equivalent terms. The logical terminology is that of thermodynamics, and all members of the conference unanimously agreed to use energy terms and units henceforth. The *water potential* (difference in free energy between the water contained in the soil or plant system and pure free water at atmospheric pressure) should be used for the quantity normally associated with total soil-moisture stress and diffusion pressure deficit or suction pressure. It is determined by three components: (1) the *osmotic potential*, which takes account of all dissolved materials in the soil solution or plant sap and is usually called the osmotic pressure; (2) the *pressure potential*, which is associated with the total pressure difference in the system, that is to say, with the difference in pressure between the water in a tensiometer and that in the adjacent soil or with the turgor pressure of plant cells; and (3) the *matric potential*, which depends on the solid matrix and the forces of retention of water in the matrix and which has been associated with terms previously called soil suction or moisture tension but which is usually ignored in plant systems.

Knowledge of the response of plants to water supply is in a less happy position than is our appreciation of transpiration. The differing responses between species, and within the one species with phase of growth, to the apparent soil–water deficit arise mainly from differences in the rate of extension of the root system, from measuring the deficit at one or two depths only, and from the difficulties associated with obtaining an integrated value of the water deficit in the soil actually occupied by roots. With increasing values of the water deficit in soil fully permeated by roots at any point of time, growth appears to decrease over the range of water potential from $\sim -0{\cdot}01$ ('field capacity') to $\sim -1{\cdot}5$ joules/gm. ('wilting point'), but the form of the relationship is modified by the level of potential transpiration and other environmental aspects. R. M. Hagan, N. S. Petinov and S. A. Taylor discussed irrigation within this context.

Survival under dry conditions—the problem of drought resistance—is still little understood. The mechanisms involved, discussed by H. R. Oppenheimer, A. M. Migahid and other contributors, are complex and numerous. Some of these, such as extensive root systems, leaf fall and stomatal closure associated with low cuticular conductance, prolong the period during which the water supply of tissue capable of growth can be maintained. The reaction of cells and tissues to drying, analysed by O. Stocker, also differ, and the behaviour of the whole plant is related to the resultant of the complex interactions which occur between varying proportions of cells of differing responses. One of the most exciting developments in this field is the hardening of plants prior to sowing which has been developed by Soviet scientists.

Increases in yield from 10 to 40 per cent are claimed. These and other contributions from the U.S.S.R. to the understanding of the reactions of plants to water and to heat were discussed by N. S. Petinov and P. A. Genkel.

The discussions will be published in two parts: (1) Reviews of research prepared as background material on "The Income and Loss of Water" (F. L. Milthorpe), "Soil Water Relations" (W. R. Gardner), "Physiological and Morphological Changes in Plants due to Water Deficiency" (O. Stocker), "Adaptation to Drought—Xerophytism" (H. R. Oppenheimer), "Methods of Research on Water Relations" (F. Eckardt), "The Management of Native Vegetation" (R. M. Moore), "Principles of Dry Land Crop Management" (S. A. Taylor), "Significance of Fallow as a Management Technique" (W. J. Staple), "Principles of Irrigated Cropping" (R. M. Hagan and Y. Vaadia), "Survey of Research on the Water Regimes of Plants" (P. A. Genkel and K. A. Bodanova), "The Water Regime of Plants on Saline Soils" (B. P. Strogonov); (2) Proceedings of the symposium, which include about forty papers contributed on detailed aspects within the above fields by workers from seventeen different countries.

F. L. MILTHORPE

MINING GEOPHYSICS

THE second Nordic Meeting for Mining Geophysics was held at Haandværkerforeningen, Copenhagen, during December 7–8. More than fifty geophysicists and technicians, including five from Finland, eleven from Norway, and eighteen from Sweden, attended. The sessions were presided over by Haakon Brækken from Trondheim, Norway, chairman of the planning committee.

The technical programme included twelve papers, two of which were concerned with Greenland. B. Sjogren (Sweden) reported on a seismic refraction and reflexion investigation on the Malmberget glaciers. The area surveyed lies about 20 km. south-east of Mestersvig, Kong Oscars Fjord, east Greenland, and the purpose of the survey was to determine the thickness of the ice–moraine layer of the glaciers. The bed-rock is mainly sandstone from the Carboniferous period which is superseded by tertiary granite. The bed-rock velocities measured varied from 4,800 to 5,400 m. per sec. while the longitudinal wave velocity in the ice–moraine layer was between 3,700 and 3,800 m./sec.; the transverse wave velocity in this layer was of the order of 1,600–1,700 m./sec. The measured thickness of the ice–moraine cover varied from 120 to 450 m. The bed-rock under the glaciers was discovered to be U-dale shaped with relatively shallow slopes while the rock walls on the sides of the glaciers climbed very steeply to about 700 m. above the glacier surface. The second paper dealing with Greenland, "A Study of the Disturbances due to Salt-water on Minor Loop-frame Indications", was presented by J. Bondam (Denmark). The survey is part of experimental measurements carried out near Narssaq, south-west Greenland.

The important problem of the elucidation of structure was illustrated by G. F. Sakshaug (Norway). Electromagnetic, magnetic, and self-potential surveys have been employed in the exploration of copper mineralization at Bidjovagge, Finmark (Northern Norway). Electromagnetic surveys have been conducted as a general reconnaissance method as well as towards the examination of detail. Electromagnetic anomalies are largely confined to beds of graphite shale occurring in the area. Magnetic surveys define magnetite-bearing greenstones. Self-potential surveys give essentially a map of the graphite shale under the moraine cover. All three methods have been essential to the interpretation of the structural relations in the area. Irregularities in the anomalies reflect tectonic disturbances, and ore-mineralizations—as diamond drilling has confirmed—are related to areas of intense disturbance. Another example of structure mapping was given by V. Munther (Denmark) in a presentation of a magnetic survey of Bornholm and its application to the geology, especially the tectonics. The island has been covered by magnetic stations in squares, the side-length being 500 metres. Moreover, a considerable number of traverses has been established, stations distances being from 10 to 20 m. apart. It has in this way been possible to correct the previous boundary lines between granite and sandstone. Known faults have been traced in more detail and older faults have been shown. In the granitic area the magnetic contours indicate the granite variety. Interpretation of the anomaly map indicated partly stronger magnetic layers at a greater depth, partly a change in the magnetic field with time. The practical aspect of the survey is the economic interest in sandstone.

A case-history was demonstrated by J. Espersen (Sweden). Magnetic and gravimetric measurements have pointed out the existence of two important and several minor ore bodies at Svappavaary near Kiruna, north Sweden. The applicability of magnetometers and gravimeters in ore prospecting is underlined by the confirming drilling results. J. Nuutilainen (Finland) described gravimetric application in ore prospecting. Levelling is carried out by means of a mercury pressure-gauge and a water tube which at the same time is the measuring tape. H. Paarma (Finland) considered magnetic gradient measurements with regard to ore bodies and structures. A report of interest concerning the conductivity of magnetite, sulphide, and different rocks sampled in Swedish mines was given by Sture Werner (Sweden). Measurements were undertaken in fifteen sulphide-mines and twenty iron-mines. The resistivity, which is the reciprocal of the conductivity, was found to amount to 300,000–3,000,000 ohm-cm. for the circumjacent rocks, while the value for magnetite and sulphide was usually found to be of the order 0·01 ohm-cm. The resistivity increases rapidly as the percentage of magnetite decreases; for example, an ore sample with 50 per cent iron has a resistivity of about 10,000 ohm-cm. For the sulphide samples the resistivity increases slowly as the percentage of sulphide decreases. Only at a very low sulphide content do the resistivity values rise.

A new instrument for measuring the curvature in bore-holes was presented by A. Holm (Sweden), and A. Breen (Norway) discussed the employment of phase-sensitive voltmeters in measuring electromagnetic fields. A point of practical importance was reported by B. Karlemo (Sweden) in a description of methods for production of geophysical maps.

At a joint evening meeting with the Danish Geophysical Society, D. Malmqvist (Sweden) gave a review of electrochemical ore-prospecting methods and emphasized the utility of this prospecting method. The 'polarization provoquée' method proposed by Schlumberger about forty years ago seems to be very suitable, especially in cases dealing with disseminated ores, and Mr. Malmqvist demonstrated some survey examples from northern Sweden.

The chairman, H. Brækken (Norway), introduced at the business meeting the very important problem of education of mining geophysicists. The meeting appointed a committee (Brækken, Werner and Tengstrøm (Sweden)) to consider the different points and to report at the next meeting.

With regard to the planning committee for the third meeting, which is contemplated within two years, the meeting appointed B. Tornqvist as chairman (Sweden), and H. Brækken, M. Puranen (Finland), and S. Saxov (Denmark) as members.

In all, the second Nordic Meeting for Mining Geophysics proved to be most successful, the attendance being about 100 per cent higher than at the first meeting at Boliden, Sweden, during November 7–9, 1956; the discussions were many and the opinion of the meeting strongly supported the arrangements for future meetings and co-operation in common problems.

THE MEDICAL RESEARCH COUNCIL

REPORT FOR THE YEAR 1957–58

THE recent report of the Medical Research Council for the year 1957–58, prepared by the Committee of Privy Council for Medical Research, adopts once more the form now used for several years (Cmnd. 792. Pp. viii+288. (London: H.M. Stationery Office, 1959.) 13*s*. net). Instead, that is to say, of giving detailed accounts of all the researches in progress, it gives articles based on certain aspects of the Council's very varied programme, the intention being to deal, once every few years, with all the important fields of research undertaken by the Council's staff. These articles are also published separately under the title "Current Medical Research" (Pp. iii+46. (London: H.M. Stationery Office, 1959.) 3*s*. 6*d*. net).

In this publication and also in the report itself we are given a description of the Council's Laboratory in Gambia, West Africa. As part of its contribution to research in tropical medicine, the Council maintains three laboratories, in Uganda, Jamaica and Gambia, respectively, and that in Gambia here described is the oldest and largest. Unlike the others, it is self-contained and is not attached to any local institution. Situated at Fajara, it was originally part of the Council's Human Nutrition Research Unit in London, but its scope has now been widened to include research, not necessarily on tropical medicine, but in other fields as well. Many research workers use its increased facilities—cardiologists, chest and other specialists, pædiatricians, public health workers and others. The centre is visited by many research workers from Britain and has lately been used by a team representing the Council's Research Group on trachoma, a cause of blindness which, because of the menace it is, is engaging the attention of research workers all over the world. This centre is also developing research on the hyperendemic malaria of the Gambia region, a region which offers special facilities for work of this kind, and this is discussed in a separate article in the report. Much of it is done at Keneba, and to facilitate communication between Keneba and the laboratories at Fajara a radio-telephone has been set up, and the Wellcome Trust has generously provided a cabin-cruiser, *The Lady Dale*, which can also be used as a floating laboratory.

As well as the article just mentioned on the hyperendemic malaria of the Gambia area, the report includes articles on the remarkable work being done by members of the Council's staff on intracellular organelles and on the enzymes contained in them. Other articles discuss the work being carried out on the viruses of trachoma and inclusion blenorrhœa, the types of the bacillus that causes Sonne dysentery, the cancer-producing viruses and their immunology, the ultra-microscopic analysis of body fluids, the performance of coal miners in hot atmospheres, the fertilization of the mammalian egg and the rehabilitation of schizophrenic people. Another article of interest discusses research in general medical practice, a line of work which is much to be encouraged. An innovation in the report is the introduction of two photographs, one of which shows *The Lady Dale*, and two line illustrations.

For the rest the report contains its usual features. Brief summaries of the work of each of the Council's research units are given, together with the names and research addresses of the Council's many workers. A long bibliography lists the varied work that these workers have published

G. LAPAGE

COMPARISON OF RAIN-GAUGES

THE measurement of precipitation is a difficult problem because of the great variations in the nature of the precipitation and of the effects of wind eddies around the gauge. The radii of liquid drops and their rates of fall range from 0·2 mm. at 0·7 m./sec. of drizzle to 5 mm. at 8 m./sec. of the heaviest thunderstorm rain, while the speed of the wind around the gauge can vary over a somewhat greater range. Solid precipitation is even more difficult to measure. It ranges from fine snow to heavy fast-falling hail-stones and may at low temperatures completely choke the gauge if, as is usual, no heating is provided for melting. In addition to these inherent difficulties, rain-gauges must be cheap and simple to operate because, on account of the great variations in rainfall from place to place, it is necessary to have many of them widely distributed. Different types of gauge have been evolved in different countries in the endeavour to meet these difficult requirements.

The ordinary British type is fixed in the ground and has a catching cylinder with a diameter of 5 in., and which is set with the rim 1 ft. from the ground. Some Continental countries fix rain-gauges to posts so that the rim is 1 m. to 1·5 m. above the ground. The shapes of the interior of the cylinders differ considerably, while in some countries the catching cylinder is contained in a much wider coaxial cone called a shield intended to minimize the effects of wind eddies.

One of the basic principles of meteorological measurement is that observations, though their absolute accuracy is to some small extent inevitably uncertain, shall be comparable. With this aim in mind, the Royal Meteorological Institute of Belgium has recently completed a five years comparison of Belgian, British, German and French rain-gauges at the Uccle Observatory near Brussels and at Yangambi in the Congo. The work is described by Dr. L. Poncelet in a recent publication by the Institut Royal Météorologique de Belgique (Publications Série A. No. 10 : Sur le Comportement des Pluviomètres. Pp. 58. Uccle-Bruxelles : Institut Royal Météorologique de Belgique, 1959). The results are analysed according to season, intensity and continuity of fall, occurrence of sunshine after rain (because of evaporation of some of the catch), and wind speed and direction. The amounts collected in individual months vary greatly from gauge to gauge and a long period of averaging is needed to produce a consistent pattern of differences. Over the whole period the differences were less than 1 per cent, with the German and French high-level gauges giving lower readings than the low-level Belgian and British gauges. Dr. Poncelet considers that different types of gauge can be compared to an accuracy of 1 per cent, and that the relation of the annual totals to the precipitation which would actually reach the ground where the gauge stands during a year is of the same order of accuracy. The accuracy is appreciably less for snow at 2–3 per cent.

Dr. Poncelet, in his capacity as chairman of the World Meteorological Organization Working Group on the International Comparison of Precipitation Gauges, has also written an article in the October 1959 edition of the World Meteorological Organization's *Bulletin* on the use of a specially designed international reference precipitation gauge. This gauge is fixed in the ground and has its rim at a height of 1 m. and is contained in a conical coaxial shield the width of which at rim-level is 1 m. Arrangements are in hand for comparisons to be made in most countries between the readings of this reference gauge and the national gauges. The latter may, it is believed, differ from one to another by 5–15 per cent. Most of the reference gauges will be made by the same (British) manufacturer. In any event, every effort is being made to ensure uniformity down to the degree of polish of the copper surface and the wetting properties of the polythene receiving bottle and measuring glass.

It is hoped that this comparison, which will take several years, will provide means of reducing rainfall observations for comparison with an accuracy of 1–2 per cent, which will permit computations of water balance to be made and rainfall maps drawn without discontinuities at national frontiers.

MEASUREMENT OF VISUAL RANGE

By Dr. P. CROSBY

Department of Supply, Weapons Research Establishment, Salisbury, South Australia

TWO photoelectric instruments have been constructed at the Weapons Research Establishment, Salisbury, South Australia, for measuring the scattering coefficient, b, of the atmosphere. Because the associated 'visual range' V is more commonly understood, it is our practice to quote the results as 'visual range' values, where $V = 3{\cdot}912/b$ (see ref. 1).

Polar nephelometer. The first instrument is a version of Waldram's polar nephelometer[2]. The light source is an ionic flash tube. The light beam is defined by a baffle-box with square apertures. A second baffle-box with a photomultiplier tube forms the photometer. The apertures are square and the field of view of the photometer passes through the light beam. The photometer is rotated about a fixed point of the light beam to receive light scattered at various angles, from 15° to 165°. The volume of illuminated atmosphere that lies in the field of view of the photometer being known from the dimensions of the apparatus, a polar diagram of scattering of the light flux scattered by unit volume of atmosphere is obtained and extrapolated over the regions 0°–15° and 165°–180°.

The polar diagrams show a strongly forward scattering, indicating that most of the scattering is from large particles.

A measurement of the intensity of the source is made by directing the photometer at the source with a very dense neutral filter in the light-path. Integration of the polar curve produces a value of b or V.

The filter is required to prevent overloading the photomultiplier. Its transmission factor is calibrated against the reflexion of light from two magnesium oxide surfaces.

Integrating nephelometer. The second instrument is a version of the Beuttell and Brewer integrating nephelometer[3]. The light-source behind a piece of opal glass is an ionic flash tube. The photometer consists of a photomultiplier tube and baffle box with circular apertures. It is directed across the opal glass towards a black box in order to receive light scattered at angles between 10° and 170°. A correction of 6–7 per cent is required to allow for light scattered between 0°–10° and 170°–180°, according to the polar nephelometer results. The amount of light flux reaching the photomultiplier is directly proportional to the scattering coefficient.

A reference measurement of the intensity of the source measured along the normal to the opal glass is required to obtain absolute values of *b*. The intensity is measured by placing a diffuse reflector above the opal glass, on the axis of the photometer, to direct light through a dense filter on to the photomultiplier.

The photomultiplier output of either instrument is measured as the voltage across a 10^5-ohm anode load using a cathode-ray oscillograph with a long-persistence tube.

Meteorologists should be particularly interested in the integrating nephelometer since it is a direct-reading instrument. First, the voltage applied to the photomultiplier is adjusted to produce a standard cathode-ray oscillograph deflexion when measuring the intensity of the light source. Then, when the photometer is receiving scattered light, the 'visual range' is read directly by noting the cathode-ray oscillograph deflexion on the special scale placed over the screen. The instrument is 7 ft. × 18 in. × 18 in. and costs less than £200, excluding the cost of the two power supplies and the cathode-ray oscillograph.

Observations are made inside a well-ventilated room. Complete darkness is not required. Experience has proved that the results obtained indoors are identical with those outdoors within the 10 per cent accuracy claimed for the system, on dull days and at night-time. Checks during sunlight are not possible, as there is too much background stray light.

The visual range fluctuates widely during any one day. Generally, visibility is between 25 and 45 miles. Lower readings are obtained on occasions. The least was 0 5 miles during a mild sandstorm. The highest was 53 miles after heavy rain had fallen. The equipment is to be transferred to Woomera to study conditions there.

The 'visual range' is, according to meteorological definition, the distance at which a dark object can be distinguished and recognized against the horizon sky. It should be noted that seldom has a meteorological office any special markers and that generally a glance outside is the only basis of the 'visibility' figure published by the office. Sometimes an inspection of various distant landmarks is made, but estimates by different observers vary widely due in part to the different luminal contrast of their eyes. In any event, the ability to see a distant object depends on the prevailing background brightness in that direction, and the presence of cloud would affect the result.

The nephelometers, on the other hand, make a direct measurement of the basic property of the atmospheric scattering which is the primary cause of loss of contrast or brightness of an object as it recedes from the observer.

Special features of the new nephelometers compared with the visual instruments are:

(*a*) Use of an ionic flash tube. This produces a high-intensity light beam which need not be concentrated further by mirror or lens systems. The latter would have surfaces on which dust could collect and form stray light. The heat energy within the light beam from an ionic flash tube is not sufficient to dry the sample of atmosphere. Continuous sources, used in visual nephelometers, produce a great deal of heat.

(*b*) Use of photo-multiplier tube. This eliminates the fatigue of visual measurement of the low intensities of scattered light.

(*c*) Automatic recording of visibility. The visibility is read directly off the cathode-ray oscillograph screen of the integrating nephelometer after the calibration has been carried out. The light source can be operated automatically and a continuous photographic record of the screen made. Alternatively, the cathode-ray oscillograph can be replaced by a pen-recording system. In either case, a chart similar to a temperature-time chart is produced and would be valuable for forecasting visibility.

This communication is submitted by permission of the Chief Scientist, Australian Defence Scientific Service, Department of Supply, Melbourne.

IONIC EXCHANGE AND THE STRUCTURE AND FUNCTION, INCLUDING MOTILITY, OF CYTOPLASMIC MEMBRANES

By Dr. W. E. HUTTON*

Department of Neurology, University of California School of Medicine,
San Francisco, California

CONSIDERABLE study has thus far yielded no adequate unified explanation of the structure and function of superficial cytoplasmic membranes. Various metabolic, or carrier, hypotheses have not been substantiated when tested. Other chemical explanations, such as the lipoid – sieve hypothesis which views membranes as static structures, are limited to certain aspects of permeability. Our present increased knowledge of ionic exchange and the realization that macromolecular constituents of the cytoplasm are capable of functioning as ionic exchangers present the possibility of an explanation of membrane structure and function based on certain principles of ionic exchange.

A key problem is the formulation of an explanation of the conversion of the chemical energy of metabolism to cellular motions; one possible explanation is a reversible hydration – dehydration of the membrane. This sort of change can be an effect of certain types of ionic exchanges and may be influenced by a variety of compounds. As outlined below, this hypothesis, that ion-exchange phenomena may produce reversible hydration, permits a unified explanation of the electrical behaviour of cells, of differential permeability and of membrane motility.

---

* Present address: Science Division, Stephens College, Columbia, Missouri.

Because of the relatively recent applications of ionic exchange principles to biology, a few general points about them should be reviewed. There are two types of cationic exchangers: strongly and weakly acidic; and two types of anionic ones: strongly and weakly basic. Particles of ionic exchange materials consist of insoluble frameworks, permeable to water and with firmly bound acid or basic functional groups. Ion exchange depends on charge density: trivalent ions displace divalent ones, and so on. Concentration of ions is also a factor. Cross-linkage is the term for the rigidity of bonding within exchange particles. The specificity of exchange depends on cross-linkage and properties of the compounds making up the exchanging particles Rates of exchange decrease with increases in cross-linkages. Exchange-rates can be decreased by the binding of large ions on particle surfaces[1].

Biological materials may act as ionic exchangers[2]. Proteins, acid mucopolysaccharides and cerebrosides are weakly ionized, whereas the sulphated mucopolysaccharides, nucleic acids and phospholipids represent strongly ionized exchangers. Proteins exchange or bind ions such as hydrogen, calcium and the polyvalently ionized macromolecules. Fibrous proteins, long believed to form part of membrane structure, may also exchange hydrogen ions for sodium and potassium. However, the exchangers appear to work better in an insoluble form. Hence, it may be of interest that these biological exchange materials can exist in the cytoplasm as particles.

There seems to be good circumstantial evidence that the membranes are composed of some sort of cytoplasmic particle. It has been possible to demonstrate both the motility of cytoplasmic membranes and pinocytosis[3]. Certain cells have been shown to take up foreign proteins by phagocytosis, pinocytosis or both[4]. These processes are something of a puzzle, implying as they do not only a transient rupture of the cytoplasmic membrane but also a rather sudden increase in the amount of membrane material as well. If membrane material is potentially particulate and if the particles are drawn from the cytoplasm as needed, these puzzles can be solved. This implies that there are cytoplasmic particles that have some properties in common with membranes. Outstanding properties of membranes are permeability to 'fat-soluble' materials and electrical phenomena; the former implies a high content of lipid, whereas the latter implies ionic exchange because of an absence of metallic conductors. Microsomes have a high content of lipid and of nucleoprotein, so they may take a role in membrane formation. However, electron-micrographs which show the superficial cytoplasmic membranes and the mitochondria do not reveal any structures that can be clearly identified as microsomes[5,6]. Perhaps microsomes are in some measure created by the stress of high-speed centrifugation, and, if so, these particles and membranes may have a common precursor. Because membranes act as a lipoid phase, it is plausible that these particles form the membrane by coalescence of their lipids.

Assuming the existence of these membrane particles, one may indicate the effect hydration would have on permeability to water-soluble substances. Hydration of the lipids of these particles, if it went far enough, would increase permeability. This permeability would not only involve materials such as the sugars, but also the water-soluble ions. Under suitable conditions a flow of ions would produce the electrical phenomena. Hence, if one understood how to hydrate or dehydrate the membranes, one could exert some measure of control over both permeability and bioelectrical phenomena. Parenthetically, one should note that these particles would be in constant motion relative to the fluids which bathe them and that this could produce a situation like that in an ion-exchange column.

Hydration and dehydration of the cytoplasmic membranes (either by direct introduction or withdrawal of water or else simply by altering its activity) imply changing composition. Introduction of fat-soluble organic compounds could affect the hydration of membrane lipids. Carboxylic acids would tend to bind hydrogen and calcium ions and thus cause some dehydration. Phospholipids, being relatively highly ionized, would tend to be hydrating agents, and they could also tend to draw other hydrated ions into the membrane. Carbonyl and hydroxyl groups would tend to be hydrating agents whether they occurred in glycolipids or steroids. Organic ions, being fat-soluble and attended by water of hydration, would tend to be hydrating agents. In the opposite direction the more nearly non-polar ethers, esters, hydrocarbons and noble gases would tend to promote dehydration.

Reversible hydration is central to the explanation of membrane motility. Under suitable conditions the membrane particles would function as weakly acid cation exchangers. Such exchangers may function as converters of the chemical energy of ion-exchange to mechanical work because they undergo large increases in volume when they exchange their hydrogen for some other ion, and large decreases in it following a second treatment with acid[1]. The basis for such effects would be the carboxylic acid groups of the membrane particles. An increase of permeability would, for obvious reasons, tend to increase metabolism. Since acid, for example, carbon dioxide, is an important end-product of metabolism, the hydrogen ions formed would tend to produce a decrease of permeability and particle shrinkage. This change would be followed by a decrease in metabolism or less acid. The hydrogen ions in membrane lipids could then be exchanged for other cations in the environment, and this would lead to swelling of particles, increased permeability and so on. These changes would give rise to bioelectric phenomena.

A hydrated membrane, because of permeability to ions, would have a low electrical resistance and might be thought of as being depolarized. As acid from metabolism displaced cations from it, the membrane would become less hydrated and offer greater electrical resistance. The binding of hydrogen ions by the membrane would leave an excess of anions in the cytoplasm which would thus be negatively charged. Depolarization might be achieved by introduction of fat-soluble ions such as acetyl choline[7] into the membrane. Depolarization-levels of such ions would depend on the relative proportions of the various 'hydrating' or other agents in the particles.

The explanation of differential permeability is ordinarily to be subdivided into two parts: selective accumulation (or the reverse) of ions and of un-ionized substances. Differential permeability to ions may possibly be explained as an exchange or displacement process. The sort of mechanism involved (bearing concentrations in mind) may be illustrated by a displacement series of cations, which is arranged in order of decreasing ability to displace crystal violet from a weakly acid silicate exchanger, as follows: putrescine, cadaverine, pyridoxine, thiamine, histamine, hydrogen, barium, acetyl choline, calcium, magnesium, prostigmine, atropine, epinephrine, and esserine[7]. The arrangement follows the principles of ionic exchange and 'ion exclusion'.

The explanation of differential permeability to un-ionized materials requires the introduction of another idea from ionic exchange. This concept (absorption or ion-exclusion) is the absorption of slightly ionized or uncharged molecules by ion-exchanger particles. Some simple rules apply to this absorption. Aromatic acids are more strongly absorbed than aliphatic ones. Non-polar substituent groups enhance and polar ones diminish this absorption. Absorption processes have made it possible to separate isomeric six-carbon sugars from each other (borate exchangers) and, by means of exchangers with optically active functional groups, it has been possible to separate optical isomers[8]. Absorption, since it can help to account for the differential binding and exchange of optical isomers, aromatic compounds, polyhydroxy compounds and lipids *in vitro*, may account for the binding of lipids to a variety of multivalent macromolecular ions in the formation of cytoplasmic membranes. If, for example, it is possible to displace one hexose by another on a borate exchange column, it would be possible to displace one hexose by another in a membrane particle where the role of borate was taken by some other residue. This is a possible mechanism of differential permeability of cells to un-ionized water-soluble compounds and an alternative to the 'carrier molecule' hypothesis.

Proposing an alternative to the metabolically derived carrier hypothesis means considering metabolism to be only indirectly connected with membrane function. The action of cyanide on mammalian erythrocytes illustrates, experimentally, the limitation on the metabolic interpretation of cell function. The action of cyanide has been assumed[9] to be due to the inhibition, demonstrated *in vitro*[10], of cytochrome oxidase. However, cyanide has also been implicated as having an effect on cytoplasmic membranes; Brinley's *Amoebae* survived injection of a dose of cyanide that was lethal, extracellularly[11].

The effect of cyanide on active transport of cations and glucose utilization in erythrocytes during an 18-hr. incubation period was studied by Maziels[12]. While cyanide in concentrations up to 10 mM/l. did not inhibit active transport, the potassium – sodium ratio was smaller and the amount of inorganic phosphate liberated was greater in cells treated with cyanide than in controls at comparable pH levels. Also, the amount of glucose utilized was greater in the cells treated. The implication of an increase in general permeability was noted in the results of this work on glucose utilization, phosphate liberation and cation ratios. Since cytochrome oxidase is of no consequence in red blood cells, the probable effect of cyanide would be to bind hydrogen ions. In terms of my hypothesis, this would lead to increased permeability.

The indication for further study along this line is clear. As the ion-exchange hypothesis provides a better explanation than does the cytochrome-oxidase-inhibition theory for the action of cyanide on mammalian erythrocytes, so through 'ion exclusion' or absorption a better understanding of structure – action relationships in drugs may be possible. Indeed, in the general application of ion-exchange phenomena to aid our understanding of biology, we may be seeing the start of a rational approach to such fields as immunology, oncology and neuropharmacology.

SCRAPIE: A TRANSMISSIBLE HEREDITARY DISEASE OF SHEEP

By H. B. PARRY

Nuffield Institute for Medical Research, University of Oxford

SCRAPIE is a chronic wasting syndrome affecting sheep in middle age, well known in Western Europe for at least two hundred years, almost always fatal and associated with degenerative changes in several organ systems. Its cause remains unknown; it can be transmitted experimentally by inoculation and some have considered the evidence available to favour a virus infection with a long incubation period[1], others a hereditary disease[2]. The literature has been reviewed recently[3].

The epidemiology• of scrapie has been studied continuously over a 7-yr. period in 70 flocks in Britain of 10 breeds with some 10,000 breeding ewes; many of the flocks are fully recorded and are closed populations except for new sires[2]. Some clinical and pathological criteria of the disease have been described[2]. Only unequivocal cases of classical-type scrapie are included in this study, which is based on 800 cases, of which the great majority were in females, only 40 being in rams. 149 cases have been autopsied. Affected animals have not been isolated in quarantine, but their progeny and close relatives have been disposed of so far as has been practicable.

The results may be summarized as follows:

(1) *Age of Manifestation.* Data are available for 526 animals—492 females and 34 males. The age of manifestation varied from 1¾ to 11 years in females and 1¼–5½ years in males; the median age in both sexes was 3 years, the mean age being 3 years in males and 3½ years in females. 8·2 per cent of all cases were manifest by 2½ years of age, 71·9 per cent by 3½, 88·0 per cent by 4½, 93·4 per cent by 5½ and 97·5 per cent by 6½.

(2) *The* 90 *per cent Manifestation Level.* As 87·6 per cent of the females and 97·0 per cent of the males manifested the disease by 4½ years old this age has been adopted, for the purpose of classification, as an arbitrary end-point at which about 90 per cent of the potential cases of scrapie may be expected; the 10 per cent developing after 4½ years of age are termed late manifestation. An affected animal is one alive and well at 4½ years old and not manifesting scrapie thereafter while under observation; an unaffected animal not under observation until 4½ years old is termed unclassified. An affected animal is one manifesting the disease at any age.

(3) *Sex Incidence.* The disease would appear to affect both sexes in similar proportions, although the data for males are few.

(4) *General Epidemiology.* The flock incidence, that is, the number affected per 100 breeding females per annum, varies widely from flock to flock, even of the same breed, and from year to year. Many flocks may be considered as free, that is, no manifest cases for at least 5 years; in many the incidence is low (1–3 per cent) or sporadic (< 1 per cent), in some it is medium (4–10 per cent) and in a few flocks it is high (> 10 per cent), and may exceed 20 per cent.

A group of flocks, each flock breeding all its own females and selecting most of its sires from flocks within the group, may be considered to be a closed breeding population or flock-group. The flock incidence varies widely between different flock-groups; several have had no cases, others many.

In an affected flock-group, many flocks remain free of the disease, although they have used sires reared in medium incidence flocks during a period when manifest cases were present.

The introduction into a free flock of a sire which afterwards manifested the disease while in the flock has not been followed by any further manifestation of scrapie, in one instance for 2½ years and in another for 1½ years thereafter.

Where sheep of another flock-group free of the disease are run on the same farm and intermingled with affected sheep, no case of scrapie has appeared in the free flocks over 3–5 years.

In recorded flocks with a medium to high incidence initially, the incidence has dropped to the low range in all but three flocks. In two of these it has not been possible to dispose of close relatives; in the third a low incidence has suddenly risen to the high level, coinciding with the female progeny of certain matings reaching the age of high manifestation.

Many flocks with a low or sporadic incidence initially have had no case for 2–3 years or longer.

We have found no evidence to suggest spread of the disease from affected animals to others of the same generation by contact, coitus or contaminated environment.

(5) *Familial Incidence.* While in individual flocks of low to medium incidence affected animals appeared to occur capriciously in different and unrelated families, when these data were studied with knowledge of the performance of the whole flock-group, it became apparent that the incidence among individuals with a close relative affected, that is, a full or half brother or sister, father, mother, aunt, uncle or grandparent, was very much higher than in individuals with no close relatives affected.

The incidence in a female age-group, that is, in the classified progeny born into one flock in one year, usually sired by 1 or 2 rams, is more variable than the flock incidence, and may exceed 60 per cent.

The incidence among the progeny of one affected parent is higher than the corresponding flock and age-group incidence; in free or sporadic incidence flocks it is usually 0–5 per cent, in medium incidence flocks 25–30 per cent, and in high incidence flocks 50 per cent.

An unaffected female producing affected progeny by one sire will usually produce unaffected progeny by other sires at previous and subsequent matings, and the pedigree of her descendants will show occasional affected individuals.

A pedigree derived from an animal with one affected parent will often show a generation unaffected, but the disease usually appears again within 2–3 generations.

The incidence does not appear to be influenced by order of birth or foster rearing of the progeny. The progeny born to mothers manifesting scrapie at the time of their gestation and suckling are often but not always affected; whether the incidence is significantly higher than might be expected is not known.

(6) *Heritability.* The manifestation of scrapie among 232 sheep coded according to the performance of their parents is shown in Table 1; the incidence observed follows closely that expected of a hereditary disorder controlled by an autosomal recessive gene.

Table 2 summarizes data for sheep with two affected parents, and for those sired by an affected ram in a flock which has had no other case of scrapie for at least 30 years, and in which the dams may therefore be presumed to be mostly homozygous 'clear'.

The occurrence of scrapie among 34 sets of gestational, probably binovular, twins is consistent with the data shown in Tables 1 and 2. One set born of 2 affected parents were both affected: of those born of an affected and an unaffected 'carrier' parent, sometimes both are affected, sometimes one and sometimes neither; while of 18 sets born of unaffected 'clear' parents, all were normal.

Of 49 progeny of affected sires and unaffected dams, 13 (26·2 per cent) were affected; of 5 progeny of

Table 1. MANIFESTATION OF SCRAPIE OBSERVED AMONG THE FEMALE OFFSPRING OF PARENTS WITH VARYING FAMILIAL CONNEXIONS WITH THE DISEASE, AND THAT EXPECTED FOR A SIMPLE RECESSIVE HEREDITARY DISORDER

Mating	Offspring No. at risk*	No. affected observed	 expected
Affected × affected	24	22	21·6
Affected × unaffected 'carrier'†	15	7	7·4
Unaffected 'carrier' × unaffected 'carrier'	6	0	~1 6
Unaffected 'carrier' × unaffected 'clear'‡	168	7	<8 2
Unaffected 'clear' × unaffected 'clear'	19	0	0

* Sum of affected plus unaffected animals under observation until the 90 per cent manifestation level at 4½ years old.

† Unaffected 'carrier' has one parent affected and/or more than one progeny affected.

‡ Unaffected 'clear' has no progeny or close relatives affected.

Table 2. MANIFESTATION OF SCRAPIE SHOWING THE CUMULATIVE TOTALS OF AFFECTED ANIMALS, OBSERVED AND EXPECTED ON THE BASIS OF A SIMPLE AUTOSOMAL RECESSIVE CHARACTER, AMONG THE OFFSPRING OF (*a*) TWO AFFECTED PARENTS, AND (*b*) ONE AFFECTED AND ONE UNAFFECTED 'CLEAR' PARENT

Age in years	½	1½	2½	3½	4½	5½	6½
(*a*) No. at risk*	93	63	42	31	30	29	28
Manifestation factor	0	0	0·08	0·72	0·88	0·93	0·97
No. affected							
Expected	0	0	3·4	22·3	26·4	26·1	27·1
Observed	0	0	5	23	25	27	27
(*b*) No. at risk*		36	27	12			
No. affected							
Expected		0	0	0			
Observed		0	0	0			

* Sum of affected plus unaffected or unclassified animals under observation up to this age.

unaffected 'carrier' sires and affected dams, 2 (40 per cent) were affected; while of 286 progeny of unaffected sires and unaffected dams, 24 (8·3 per cent) were affected.

The incidence among one age-group of 32 females sired by 3 rams in a flock with a very high incidence throughout the relevant 5 years was 34 per cent. Among the daughters of an affected ram it was 50 per cent, of an unaffected ram 14 per cent and of an unclassified ram 20 per cent.

(7) *Selection.* There is a special bias towards the selection of individuals which have made exceptionally rapid growth in infancy and adolescence with particular development of the skeletal musculature, for such animals tend to win the principal awards at our leading agricultural shows. Many 'show' winners of high excellence have close relatives affected, have affected progeny, or may even manifest the disease later.

(8) *Experimental Transmission.* 5 of 5 lambs inoculated intracerebrally with a brain suspension from a representative affected animal developed a scrapie-like disease 14–24 months thereafter; 5 controls showed no clinical abnormality.

These results are difficult to reconcile with the concept of an infectious disease of the usual communicable type.

The results lend strong support to the view that scrapie is primarily a hereditarily determined disease and establish that the clinical manifestation of the disease is highly heritable.

The results are consistent with the hypothesis that scrapie may be due to a single pair of alleles behaving in a simple Mendelian autosomal recessive manner. It is not possible to rule out other modes of inheritance, notably dominance with variable expression, or to assess the influence of modifying genes and of environmental factors upon manifestation.

As this hereditary scrapie can be transmitted by inoculation, a feature of scrapie amply demonstrated by others[4-6], it is suggested that in the homozygous recessive individual a substance, the transmissible scrapie agent, is formed which is closely associated with the development of the degenerative changes in several organ systems. Transmissible scrapie agent can be demonstrated in many organs[4,5], it is self-replicating[4,5] and its presence can be demonstrated in the experimental disease prior to the onset of clinical signs[5]. It is unusually stable to heat and chemical agents[5,6]. The immunological tests commonly present in virus infections are negative in scrapie[7].

It is postulated that scrapie is a hereditary disease of unusual type, in which the undesirable, indeed lethal, effects of the genotype are mediated through a positive factor, probably chemical in nature, which does not provoke the immune responses usual with self-replicating microbial infections. This concept would go far towards providing a satisfactory explanation of the facts at present known regarding scrapie. Further long-term studies will be necessary to provide adequate data to confirm the hypothesis, to elucidate the role of transmissible scrapie agent in the functional and anatomical pathology of the disease, and indeed to establish whether or not 'scrapie' represents more than one aetiological entity. A detailed report is being published elsewhere.

The generous support of the Nuffield Foundation has made this study possible.

THE PLEXIFORM ZONE AND SHAPE RECOGNITION IN THE OCTOPUS

By DR. J. A. DEUTSCH

Center for Advanced Study in the Behavioral Sciences, Stanford, California, and Institute of Experimental Psychology, Oxford

IT is the purpose of this article to suggest a possible structural basis for shape recognition in the octopus. The octopus is now the best-investigated animal in respect of its discrimination of visual shape, and this is chiefly due to the work of N. S. Sutherland. This author has also put forward a theory to account for his findings[1], but this theory was criticized by Dodwell[2] on grounds which seem to me to be substantially correct. The cephalopod visual system has also been studied from the neuroanatomical viewpoint by Kopsch[3], Lenhossek[4] and Cajal[5]. The present work is an attempt to infer the way the well-defined neural structures, uncovered chiefly by Cajal, result in the behavioural properties which the octopus displays when discriminating shape.

The System

The basis of the system is an arrangement which converts the distance between two points into an output, the size of which is inversely proportional to the distance. That is, the larger the distance between two imposed points the smaller will be the output, and the smaller the distance between the two points the larger the output.

This operation is performed by an arrangement of the following form. There is a set of lines running parallel to each other. Each line is interrupted at randomly chosen points, so that each line is divided into a number of segments of varying size.

Into this set of parallel segments enter at right angles a set of other lines (to be called retinal receptor fibres). These enter the layer of segmented lines at equally spaced intervals and penetrate the layer of the segmented lines to its other boundary.

Now let us assume that the retinal receptor fibres become active when they have been stimulated by a boundary discontinuity. The distance between two retinal receptor fibres reflects the distance between two points on a boundary. Let us also assume that the line segments in the parallel line layer also become active only when two or more than two simultaneously active retinal receptor fibres cross them. It will then follow that the closer together the two active retinal receptor fibres are, the greater the number of line segments will become active. The sum of active line segments in the parallel line layer will correspond in inverse ratio with the distance apart of the active incoming retinal receptor fibres.

The arrangement which has been described corresponds with what can be seen of the histology of the 'zona plexiforme' of the deep retina as described and illustrated by Cajal[6]. Fig. 1 shows the terminations of the incoming retinal fibres. Fig. 2 shows some of the fibres which may be identified with the segmented parallel line layer of our arrangement. It is to be seen that each of the segments in the section has an output leading out of the 'zona plexiforme' farther into the optic nervous system. We simply have to assume that the fibres in this figure act as a 'coincidence gate' or a spatial summator. If we make this assumption, then arrangements such as these have the function of converting distance between fibres into numbers of impulses. Distances or intervals can then be handled in the same way as intensities. Such a transducer of relational properties does not rely on 'scanning', with its high requirements of timing accuracy and overall precision. Such an arrangement would therefore have implications in the phenomena of neural integration beyond those of cephalopod vision.

So far, the arrangement described would transform the distance between a pair of points into an amount of neural activity The shapes to be discriminated, however, are composed of a great number of pairs of points. It is assumed that these pairs lie on lines parallel to each other and that each pair is measured by an arrangement such as was described above. This is done by having many such arrangements side by side, parallel to each other, running in the vertical visual axis. It is assumed that the total amount of excitation generated by the whole set of these arrangements gives the octopus its chief cue to the discrimination of shape. Different shapes are in this way translated into a single continuum of amount of activity. The problem of discriminating between them becomes one of differentiating between various levels of activity in a single channel.

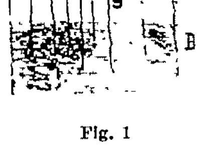

Fig. 1

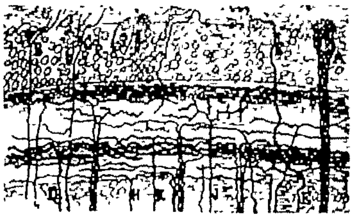

Fig. 2

Before proceeding, I should make clear that for the purposes of prediction two accessory assumptions must be made: (1) that vertical lines produce little or no output, because excitations on the same vertical arrangement inhibit each other over a small distance, and (2) that the octopus can also discriminate relative vertical positions of the output converted in the above way. This second appears to be a residual factor left when we have explained the rest of Sutherland's results. We may assume that it is an independent channel which signals these differences also as differences in quantity of output. It should also be stated that the present system has been left quantitatively flexible. It has been assumed, for example, that the vertical distance between two points leads to an output which is the reciprocal of this distance.

There is no reason for supposing that the conversion is precisely this. The theory only has to assume that the conversion is something like this, and then perhaps not over the whole range (for example, the system may collapse over very large visual angles).

Properties of the System

(1) *Transfer to different sizes of the same shape.* Let us take two parallel lines and their scale enlargement, and place them at right angles to the arrangements described above (that is, in the horizontal visual axis). The total amount of discharge from the system outlined above for the two figures will be the same. If we double the vertical distance between the lines, the amount of firing from each pair of points will halve. However, as we double the distance between the two lines, we also double their length. If we double their length we measure from twice the number of arrangements (as they run parallel to each other in the vertical direction). Therefore, the total amount of output given of both sets of lines separately will be the same. Transfer should therefore be excellent in the case of this shape.

Transfer from one size to another will depend on two factors: (*a*) the shape used; and (*b*) the other member of the pair from which the octopus has learnt to make the discrimination.

As regards the first point, it will be readily seen that, if we take a V shape lying on its side and a scale enlargement of it, the scale enlargement will produce a greater output. The small V shape is a part of the larger V shape. Such reasoning will apply to diamonds and triangles, *inter alia.* However, any scaling down (or scaling up) will subtract only the pairs of points (or add pairs of points) which are the most distant from each other on the vertical axis. These will be contributing disproportionately little to the total amount of output.

This brings me to the second point. If the total amount of output from the shape to be discriminated from the other member of the pair was larger, then the increase in output due to the enlargement of this shape will not destroy the discrimination, because the effective distance along the continuum is increased. (". . . the octopus, having been trained to discriminate between vertical and oblique, treats the horizontal in transfer tests as equivalent to the oblique (and vice versa for animals initially trained to discriminate between horizontal and oblique)"—Sutherland, 1958. p. 45*b*.) There may actually be an improvement if the other parameters which the octopus derives from the stimulus also increase the distance between discriminanda.

Sutherland has frequently noted that the octopus is capable of maintaining a discrimination between two shapes even when their size is altered (within certain limits) (for example, Sutherland, 1957*a*, p. 65, 1957*b*, p. 13). He has noted that a decrease in size shows a smaller transfer than an increase. This would be predicted on the present theory with certain pairs of figures where the distance along the continuum of output was decreased.

However, a breakdown of the size transfer data according to the shapes to be discriminated has not been considered. A search of Sutherland's data, however, reveals that there is a difference in the predicted direction (Sutherland, 1958). The animals were trained to discriminate between a square and a triangle, both 25 sq. cm. in area. Transfer tests to larger squares (36 sq. cm.) show 65 per cent correct responses. (The accuracy of responding to the original square under the same conditions is 65 per cent.) The figure for transfer to a small square is 67·5 per cent. However, transfer to larger triangles yields a score of 88 per cent in the case of the larger and 67·5 per cent when the triangle is made smaller (changes in area equal to those made in the case of the squares). As a triangle of the same area produces a much larger output than the square, an increase in the size of the triangle will increase the difference in the amount of output between the triangle and the square. Changes in the size of the square will not produce changes in output, if we assume (assumption 1) that its vertical lines produce little or no output. Transfer here should not vary with the direction of the change of size.

The theory is thus in agreement with what is known of the ability to transfer from one size to another in the octopus. Further testing of the theory should examine the relation between shape and the capacity to transfer to other sizes, and also the relation between size transfer and the other member of the pair to be discriminated. We should expect on this theory not only transfer of size to be relative to the other member of the stimuli to be discriminated. Even if the present theory is wrong, it will have been important if it directs attention to these two factors, which so far have been neglected.

(2) *Difficulty of discrimination between shapes.* The difficulty of discrimination on this theory should be proportionate to the difference in the quantity of output generated by the two shapes to be discriminated. Each pair of points on the boundary of the shape where it cuts a vertical arrangement will produce an output which will be inversely proportional to the distance of the two points. The sum of the outputs produced by all the pairs of points will characterize the shape for the octopus. The shape, regarding this mechanism only, will be represented as a quantity, or a number on a single dimension. The calculation of similarity can therefore be made with rigour. An index of similarity will be the difference between the two quantities generated by the two shapes to be discriminated. (Such a formulation assumes that the message on all other visual discrimination mechanisms is kept constant, such as that mentioned in assumption 2 (below). There are also others such as brightness, but these are easy to keep constant.)

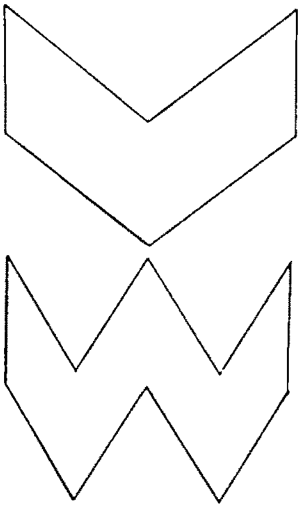

Fig. 3

(1) Sutherland[illegible] finds that horizontal rectangles are easily discriminated from vertical of the same proportions. This is readily explained. The horizontal rectangle stimulates a large number of vertical arrangements with a set of points relatively close to each other vertically. It is to be remembered that points close to each other produce a larger output than points farther apart. However, the vertical rectangle stimulates a relatively smaller number of vertical arrangements and by pairs of points farther from each other. There should, therefore, be a very large difference (1 : 25) between the outputs if the rectangles are 10 cm. × 2 cm.

"Perfect transfer occurred where the ratio of long to short sides was altered from 10 : 2 to 7 : 2 or 7 : 1" (Sutherland[1]). This would be an alteration at 1 : 25–4 : 49 and 1 : 49 in the amount of output in the discrimination. However, the absolute quantities of output would be different here also. As the direction of the ratios and of the difference remains the same here, this result does not count against the theory and, if anything, supports it. It is a result worth quoting because it shows that in circumstances where the differences among the two discriminanda are large, transfer occurs within a wide margin. It is as if the octopus was simply learning larger–smaller output differences. What would happen if larger numbers of shapes had to be retained in the same experiment by the octopus would be of interest. Further, these results show that if the two shapes to be discriminated give large differences of output, 'size-constancy' for the octopus does not need to be notably accurate.

(2) Sutherland[6] finds that two oblique rectangles (╱ and ╲) are indiscriminable. Here the sums of the outputs in the vertical arrangements are the same.

(3) Furthermore he stated[6]: "The finding that a vertical rectangle is more readily discriminable from an oblique than is a horizontal was unexpected". Such a difference is readily predicted from the present theory. The horizontal rectangle would produce a much greater output than the vertical rectangle. The output of the oblique rectangle would not be intermediate as might at first sight appear because the tilt of the figure would produce a set of points close to each other at the corners on the vertical axis. It is predicted that if the corners of the horizontal figure were altered to make it into a parallelogram with the short sides parallel to the vertical visual axis (the area being kept the same) the differential discrimination would disappear.

(4) Sutherland[7] has found that V and W shapes (Fig. 3) of the same height, width and area can be discriminated with great difficulty or not at all (accuracy 53 per cent) when the figures are in this orientation. An inability would be predicted on the present theory. The total vertical distances are the same in both cases. However, it would be predicted that the same shapes would be more discriminable when both are tilted through 90°. With ⩽ the vertical distance is divided into more short segments than in the case of <. Therefore, as short segments produce more output than long, and there are here more short segments, output should be larger for ⩽ than <.

(5) Sutherland[7] has found that ∨ is indiscriminable from ∧ (accuracy 50 per cent). This can be predicted in a straightforward way. He has also found that < can be discriminated from ∧ (though only with an accuracy of 56 per cent). The < shape would cut the vertical arrangements at points closer to each other than the ∧ shape, thus producing more excitation. However, ∧∧ is discriminated from > with greater ease (69 Per cent accuracy) and the present theory cannot readily account for this or the quantitatively small success of the octopus with < against ∧. (There are, however, assumptions about the sensitiveness to alterations in output with equal inaccuracies of verticality which differ for the shapes used and the amount of the shape deleted due to assumption 1 which could be made.)

(6) Sutherland (1958*a*) has found that octopuses have more difficulty in discriminating a diamond (a square with base at 45° to the horizontal) from a triangle than in discriminating a normal square from a triangle. This again is in accordance with the calculations of differences of magnitude of output derived from the theory. Though the other findings on the discriminability of the standard geometrical shapes (circles, triangles, etc.) show good agreement with the theory, differences in height (assumption 2) equally well account for some of the findings, as shapes of equal area were used. A further point to be borne in mind is that so far the assumption has usually been made that the placing of the shape on the receptor field of the octopus relative to the vertical has been geometrically exact, and departures from this have not been considered. However, the output of some shapes is much more affected by deviations. It is possible that the octopus uses this magnitude of oscillation about a mean to effect some discrimination. This supposition could be tested by imposing known and differing degrees of rotation in one direction and then the other in quick succession on the same shape, one amount serving as the positive signal and the other as the negative.

(7) It is found that the octopus can discriminate some up–down mirror images. This would be covered by assumption 2. However, left–right mirror images are indiscriminable, and this agrees with the theory.

Discussion

In the previous section, the salient reported findings on the shape discrimination of the octopus have been discussed in relation to the proposed system. The reader must be the judge of the success of the system in accounting for these findings. Predictions have also been made which allow the theory to be tested behaviourally.

However, the theory is not simply behavioural, and in this sense it is of much wider scope. A functional significance is suggested for a neuronal network of a kind to be found in many other places. It is proposed that this network converts relative distance into an output simply of quantity, and a simple *modus operandi* is given. In this way a look at the neurohistology may give a clue to the component operations on information in neural systems the overall function of which is already known. Direct work correlating visual input with events in the cephalopod optic lobes can also be used to check the correctness of my surmise.

On a more general plane it is conjectured that the octopus breaks down its visual information into various 'components' or dimensions of which the system put forward is only one. Each of these 'components' (given varying visual input) will vary only in amount. This amount for each 'component' is presumably represented as a quantity of excitation leaving the optic lobes, via one of the nerve fascicules. If this is correct, then sectioning one of these bundles, while conducting behavioural tests, would reveal the kind of classification or breakdown of the visual environment which the octopus performs by noting resulting confusions. Similarly, recording from these nerve bundles (should this prove feasible) while the eye is stimulated with various inputs should prove revealing. It is indeed possible that the transformation of shape into a simple quantitative continuum may prove to be a paradigm of the way that the problem of perceptual classification is dealt with in other organisms. In this way a given environment could be translated into a set of levels of activity in a number of channels. Thus a state of affairs for the organism could be represented as a point in an *n*-dimensional space.

My thanks are due to Prof. T. H. Bullock for discussion and encouragement, to Prof. J. Z. Young for helpful correspondence and neuroanatomical data, to Dr. N. S. Sutherland for discussion of his results, and to Dr. G. A. Horridge for helpful comment.

GEOMORPHOLOGY

Bedrock Corrosion and Drainage Initiation by Seepage Moisture on a Gritstone Escarpment in Derbyshire

A SURVEY has been made of the podsolized soils, the morphology and the drainage of the areas known as Matlock Moor, Farley Moor, Tower Moor and Blackbrook Moor, which together form the larger part of the upper reaches or 'source basin' of the Bentley Brook, a tributary of the Derbyshire Derwent[1].

Observations have been made which show the corrosive action upon the underlying bedrock of water seeping through a 2-ft. deep layer of sandy colluvial material occupying a seepage hollow at the head of the brook. Such water, slow-moving, and with an appreciable content of humus, seeping vertically on to the bedrock, has corroded it to depths of 18–22 in. The layers below 18 in. in the whole profile are permanently wet and have been so even in the dry summer of 1959. The upper mineral layers of the profile are lacking in particles finer than 0 06 mm.; but it is not yet certain whether such particles are removed by normal vertical seepage to be redeposited at lower levels, or are removed by lateral movement of soil water, near the surface, in the wettest periods of the year.

Other observations provide evidence of the processes associated with the initiation of a semi-dendritic drainage pattern on a dip-slope, of less than 5°, adjacent to the hollow, and on the scarp slope to the west, overlooking the Sydnope valley. Integrated narrow seepage lines express themselves as overdeepenings of the solum upon such slopes, though there is no surface indication of their presence. A close grid of augerings across and along them shows significant changes of soil profile morphology both within the seepage lines and on the areas between them. These seepage lines link up with visible surface drainage at lower levels.

These two types of seepage action which affect the bedrock on the watershed between opposing dip and scarp streams do not suffice to break the crest of the escarpment. As a result of their headward extension, the seepage catchment of the watershed area becomes so small that the processes of corrosion and overdeepening can no longer continue except at some point downslope where enough moisture can assemble. Hence the crest is exhumed to form a rock platform on which tors may develop wherever the wide spacing of the master joints permits their survival.

The observation that a rock platform on the watershed between two opposing drainage systems may not only be preserved, but may actually broaden by exhumation, calls for a reappraisal of the current ideas on col-formation in the normal cycle of erosion, at least on uniformly hard rocks. It also leads to a hypothesis of tor formation applicable to some of the tors of the southern Pennines. The tors in question are formed during the gradual emergence of crestal rock platforms from adjacent bands of corroded bedrock and colluvial material. These successive bands form Penck's convex and intermediate slopes[2], although they are produced by seepage, not by drainage in visible channels.

The colluvium merges into a band of thin soils which then merges downslope into a mass of valley-head peat wherein the permanent source of integrated drainage is found. The peat often rests upon the rock identical with that of the tor. The rock is pierced in a pronounced knickpoint by the stream, which flows down over lower gritstone beds and intervening partings of shale before entering the wide main valley which is cut in the dominantly shaly rocks below the lowest grit and above the limestone.

There exists a possibility of assessing the period of time necessary to exhume these tor features. Most of them are 14–16 ft. in height. Young's estimate of surface lowering of the whole area of a small drainage basin, 17 miles to the north of the area considered here, is 0 005 in. per annum[3]. If one assumes a height of 15 ft. and that the tops of the tor features have not been lowered by weathering, then the time at which they began to be exhumed should be 36,000 years ago—a date which closely corresponds to the waning of the York glacier[4].

A more detailed account of this work will appear elsewhere. My thanks are due to Dr. G. Dury and Mr. R. A. G. Savigear for their comments and advice. This work has been supported in part by a grant from the Central Research Fund of the University of London.

GEOLOGY

Mid-Tertiary Stratigraphical Palæontology

IN the course of extensive economic palæontological researches based on world-wide investigations, it has been found necessary to review and re-assess the bases of mid-Tertiary correlation and dating. We confirm the validity of the five-fold subdivision of the Oligocene and Lower Miocene as represented by the faunas of the type localities of the Lattorfian, Rupelian, Chattian, Aquitanian and Burdigalian. These five faunal assemblages can readily be correlated through to Southern Europe, the Mediterranean, the Middle East, East Africa, Pakistan and India, and the Far East as a whole.

Although the classical type assemblages are mainly developed in a molluscan–echinoid facies we confirm that it is possible to correlate these facies with beds in Southern Europe, which also contain important and characteristic foraminiferal faunas which can readily be followed through to the Far East, notwithstanding that minor stratigraphical and taxonomic revisions of older work are necessary.

In brief, beds equivalent to the Lattorfian are characterized by *Nummulites intermedius* and *N. vascus* without *Eulepidina*; the equivalents of the Rupelian are characterized by the persistence of *Nummulites intermedius* and *N. vascus* and the appearance of *Eulepidina*; the equivalents of the Chattian (where confirmed) are characterized by the persistence of *Eulepidina* and other Rupelian Foraminifera, but all true *Nummulites* had become extinct. Following the mid-Tertiary stratigraphical break, the equivalents of the Aquitanian (forming the lowest beds of the Miocene) are characterized by the persistence of *Eulepidina, Spiroclypeus* and *Miogypsinella complanata,* and the incoming of many forms, such as *Miogypsina* s. str., *Meandropsina anahensis* and *Miolepidocyclina,* which constitute part of the Neogene evolutionary surge; the Burdigalian equivalents are characterized by such forms as *Ostrea latimarginata, Borelis melo curdica, Flosculinella bontangensis* and *Taberina malabarica,* by the persistence of *Miogypsina* and *Austrotrillina howchini,* and by the appearance of *Borelis melo,* but *Eulepidina* and *Spiroclypeus* had become extinct.

It can be evaluated from the above that in the Far East the '*c*' stage is probably Lattorfian, the '*d*' stage is Rupelian, the '*e*' stage is Aquitanian, and the 'f_{1-2}' substages are Burdigalian; the presence of the Chattian is not proved. Besides the fossils mentioned above there are many others which substantiate the above conclusions.

Within the equivalents of the five classical stages there is a succession of planktonic foraminiferal faunas (Globigerinaceae) which appears to be constant wherever found and studied. These planktonic successions can be firmly dated in terms of the classical stages by their associated faunas; they permit accurate age determination of marine faunas in the western hemisphere, where, because of relative isolation, few benthonic fossils are in common with their Eurasian and African equivalents.

It has been possible to demonstrate the equivalence of the Caribbean zones of *Globorotalia fohsi fohsi, G. fohsi lobata* and *G. fohsi robusta* to the Burdigalian. The Aquitanian seems to be equivalent to all the planktonic foraminiferal zones erected by Bolli (1957) for the Cipero formation of Trinidad below the *G. fohsi fohsi* zone; consequently, all the Vicksburgian and its equivalents are Aquitanian. The evolution of *Orbulina,* known to occur in the upper part of the *Globigerinatella insueta* zone of the Caribbean, also occurs in the highest Aquitanian of the Mediterranean and Australia; this correlates with the first appearance of *Orbulina* in the upper '*e*' stage of the Far East.

It seems to be very important to note that, on the basis of the succession of planktonic foraminiferal faunas, no Oligocene can be recognized in the marine sediments of the western hemisphere, as far as published records show. This absence of Oligocene has now been confirmed by the discovery of a planktonic foraminiferal fauna associated with true Oligocene larger foraminifera such as *Nummulites intermedius* and *N. vascus* in East Africa. This planktonic foraminiferal fauna is being described elsewhere; it is noted here as having common elements with similar faunas seen in the Rupelian of south Germany and that described by Russian workers. This fauna has never been recorded or observed by us in Central American areas, and is missing precisely where we place the major stratigraphical break in that region.

The absence of marine Oligocene in the Central American region is again confirmed by the presence of *Miogypsina* s. str. associated with *Eulepidina* and of *Pliolepidina* in the lowest post-Eocene of the well-known southern Trinidad succession, which contains the oldest known post-Eocene planktonic zone of the Caribbean. True *Nummulites* (as distinct from *Palæonummulites*) is absent above the Eocene in the Caribbean.

Palæonummulites Schubert 1908 (type species *Nummulina pristina* Brady 1874) is regarded as a prior synonym of both *Operculinella* Yabe 1918 and *Operculinoides* Hanzawa 1935. The lectotype of *Palæonummulites pristina* (Brady) has been isolated and it will be described elsewhere, together with an emendation of the genus.

The genus *Pliolepidina* H. Douvillé 1915 is now regarded as a prior synonym of *Multicyclina* Cushman 1918, *Multilepidina* Hanzawa 1932, *Cyclolepidina* Whipple 1934, and *Pliorbitoina* Van de Geyn and Van der Vlerk 1935. It is believed that all species referable to this genus, whether originally recorded from the Far East, the Mediterranean region, East Africa, or Central America, are of Miocene age. The large and significant unconformity present in the Central American region is marked by the presence of much re-working of material into the basal Miocene and this has given rise to much stratigraphical confusion as to the age of the beds in question. Indeed, many of the lowest Miocene beds present have been dated as Eocene, purely on the presence of re-worked Eocene fossils, but the occurrence of *Pliolepidina* often shows that they are of lowest Neogene age; examples are the San Fernando formation of Trinidad and part, at least, of the Gatuncillo formation of Panama.

Full details of our work will be published in the near future elsewhere, together with a full bibliography.

Oriented Quartz Inclusions in Garnets

METAMORPHIC garnets in the Central Highlands of Scotland frequently contain oriented inclusions of quartz, which throw light on the mechanism of deformation of the latter mineral. In particular, garnets which have an S-shape arrangement of inclusions and have consequently grown at the same time as deformation show a variety of morphogenetic types of quartz grains, which were incorporated into garnet as inclusions.

In a specimen of mica-amphibole-garnet schist from the River Tummel (National Grid No. *NN.* 899605) there are three types of such grains. In the centre of the garnet there is a number of crescentic inclusions (about 0·05 mm. × 0·01 mm. in size), which have no visible strain shadows, glide lamellæ or deformation bands, but which in cross-polarized light are nevertheless optically inhomogeneous, although even at high magnifications the constituent units responsible for the inhomogeneity cannot be recognized. Associated with these grains, but continuing towards the periphery of the garnet, there are much larger elongated quartz inclusions (about 0·15 mm. × 0·1 mm. in size) which are optically homogeneous and are not crescentic in shape. Lastly, at the periphery of the garnet there are relatively equidimensional grains, again much larger than the first variety (0·1–0·15 mm. across), and which may have strain shadows when the grains are continuous into the matrix.

In the crescentic inclusions the average optic axis of the constituent quartz is normally slightly oblique to the elongation of the inclusions, while in the elongated optically homogeneous variety the optic axis tends to be parallel to the elongation of the grain. In the peripheral grains no constant relationship can be established between the position of the optic axes and the dimensions of the inclusions. The S-shape trend of inclusions implies that the innermost grains have been included into the garnet early in the process of movement, while the outermost individuals record the immediately post-movement stage of lattice re-organization. It is clear that throughout the deformation the fabric of the rock coarsened progressively and that the early dimensionally oriented fabric is conditioned by movement, whereas the later fabric did not develop dimensional orientation, and was presumably formed under static conditions. Since at an earlier stage the sites now occupied by the dimensionally unorientated fabric must have had quartz grains like those preserved in the interior of the garnet, the peripheral quartz has suffered severe re-organization.

Fellows[1] recognized that deformed crystalline quartz undergoes first recrystallization and then neo-crystallization. In the garnet described, the crescentic inclusions reflect the initial deformation, while the elongated optically homogeneous grains have recrystallized. These grains are analogous to mimetic mica flakes, and those in the matrix, according to this interpretation, are neo-crystalline. Both recrystallization and neo-crystallization are recognized in metallurgy by Burke and Turnbull[2]. The deformed crescentic grains can be interpreted as polygonized grains (cf. Cahn[3]) retaining their initial fine deformation texture, which is not resolved under a microscope. On the other hand, the strain-shadows in the peripheral grains must have originated during an episode of renewed deformation which succeeded the neo-crystallization.

The fact that there are slight differences—in the relationships of the optical orientation and elongation—between the crescentic (polygonized) and recrystallized grains suggests that recrystallization affects the overall lattice orientation, and that this factor must be considered when the behaviour of metamorphic quartz is studied.

PHYSICS

A Theory of Ball Lightning Formation

In a paper which has recently attracted a considerable amount of attention, Kapitza[1] has proposed a standing electromagnetic wave description of ball lightning. His paper presents a good qualitative explanation of this effect in terms of the resonance absorption of a standing wave due to a conducting ionized sphere of plasma, occurring when the wavelength of the radiation is approximately four times the diameter of the fireball.

It is the purpose of this communication to point out that a polarized electromagnetic standing wave can actually produce containment of charged particles in the neighbourhood of its electric nodes, and that this effect should be important in the initial stages of fireball formation. As a result of this investigation it has been shown that it is possible for electrons to acquire sufficient energy in the electric node regions to produce further ionization by collision, provided that the standing electromagnetic wave yield-strength is in the vicinity of 10^6 V./m. At first sight this figure may seem unusually high; nevertheless it should be recalled that field strengths of this magnitude are already required to cause atmospheric breakdown during thunderstorms. It is proposed, therefore, that the atmosphere is initially very weakly ionized (due to the thunderstorm) and that the regions around the electric nodes rapidly become highly ionized due to electron ionization by collision, building up in an avalanche fashion until the plasma frequeney ω_p is greater than the frequency of the applied field ω. At this point further field penetration of plasma becomes impossible, so that surface absorption of energy becomes responsible for maintaining the fireball in a manner similar to that suggested by Kapitza. Moreover, the spherical shape of fireballs fits into the ultimate surface absorption picture quite well, since this is a direct consequence of the fact that the configuration of minimum surface energy requires a spherical distribution.

The actual containment of a charged particle in a polarized standing electromagnetic wave will be demonstrated using a straightforward technique similar to that developed by R. Wuerker (unpublished private communication) and Cushing and Sodha[2].

We shall assume that a polarized standing electromagnetic wave can be represented by

$$B = B_0 \sin \omega t \cos \frac{2\pi x}{\lambda} \hat{k} \qquad (1)$$

$$E = -cB_0 \cos \omega t \sin \frac{2\pi x}{\lambda} \hat{\jmath} \qquad (2)$$

where B_0 represents the maximum value of oscillating field of frequency ω, and wave-length λ, and $\hat{\imath}$, $\hat{\jmath}$, $\hat{k}$ are the usual cartesian unit vectors.

The following equations of motion of a charged particle may be derived using equations (1) and (2) and the Lorentz force equation:

$$\ddot{x} = \frac{eB_0}{m} \dot{y} \sin \omega t \cos \frac{2\pi x}{\lambda} \qquad (3)$$

$$\ddot{y} = -c\frac{eB_0}{m} \cos \omega t \sin \frac{2\pi x}{\lambda} - \frac{eB_0}{m} \dot{x} \sin \omega t \cos \frac{2\pi x}{\lambda} \qquad (4)$$

$$\dot{z} = 0 \qquad (5$$

Integrating equation (4) we immediately obtain :

$$\dot{y} = -\frac{c}{\omega}\frac{eB_0}{m}\sin\omega t\sin\frac{2\pi x}{\lambda} + C \qquad (6)$$

where the constant C represents the initial velocity of the particle in the y-direction at time $t = 0$.

Direct substitution of equation (6) into (3) gives :

$$\ddot{x} + \frac{c\omega}{4}\left(\frac{eB_0}{m\omega}\right)^2\left\{1 - \cos 2\omega t\right\}\left\{\sin\frac{4\pi x}{\lambda}\right\} = \frac{eB_0}{m}C\sin\omega t\cos\frac{2\pi x}{\lambda} \qquad (7)$$

Equation (7) is clearly a difficult equation to solve ; however, if we concern ourselves with solutions of (7) representing oscillations of small amplitude about the electric field nodes, we may write :

$$\cos\frac{2\pi x}{\lambda} \simeq 1 \qquad (8a)$$

$$\sin\frac{4\pi x}{\lambda} \simeq \frac{4\pi x}{\lambda} \qquad (8b)$$

and equation (7) can be reduced to the form :

$$\ddot{x} + \frac{1}{2}\left(\frac{eB_0}{m}\right)^2\left\{1 - \cos 2\omega t\right\}x = \frac{eB_0}{m}C\sin\omega t \qquad (9)$$

which is in the form of a driven Mathieu equation. The solutions of the Mathieu equation have bound or unbound characteristics depending upon the choice of parameters[3]. For example, when :

$$\frac{1}{2}\left(\frac{eB_0}{m\omega}\right)^2 < 0{\cdot}65 \qquad (10)$$

the system operates in the first region of stability, and the solution of equation (9) takes the following bound form :

$$x = F\left\{\cos\omega_0 t - \frac{a}{8}(1 + \sqrt{a})\cos(2\omega - \omega_0)t - \frac{a}{8}(1 - \sqrt{a})\cos(2\omega + \omega_0)t + \ldots\right\} + G\left\{\sin\omega_0 t - \frac{a}{8}(1 + \sqrt{a})\sin(2\omega - \omega_0)t - \frac{a}{8}(1 - \sqrt{a})\sin(2\omega + \omega_0)t + \ldots\right\} \qquad (11)$$

where F and G are constants of integration and ω_0 represents the oscillating frequency of the particle about the electric node along the x-axis. Where we have defined :

$$a = \frac{1}{2}\left(\frac{eB_0}{m\omega}\right)^2 \qquad (12)$$

and

$$\omega_0 = \frac{eB_0}{\sqrt{2}m}\sqrt{1 + \left(\frac{eB_0}{4m\omega_0}\right)^2} \qquad (13)$$

It is convenient to represent the harmonic binding of the particle about the node by means of an effective potential. In the first region of stability this assumes the form :

$$V(x) = \frac{1}{2}\left(\frac{m}{e}\right)\omega_0{}^2x^2 \text{ volts} \qquad (14)$$

By the substitution of condition (10) into equation (6) it is possible to find the y-motion about the electric nodes, and it has been shown that the charged particle is quasi-bound in this direction. The particle will describe Lissajous's figures in the xy plane, with dominant frequencies of ω_0 and $(\omega-\omega_0)$ in the x and y directions, respectively. Having convinced ourselves that a charged particle can be bound in the vicinity of an electric node, it will suffice to say that a corresponding investigation of solutions in the neighbourhood of the electric anti-nodes yields no bound solutions ; in fact, indicates that the particles are pushed away from the anti-nodes toward the nodes. Although a charged particle is essentially contained in the x–y plane, it is clear that there is no binding in the z-direction. Nevertheless the x–y binding will allow the particle to be 'contained' in such a manner as to allow it to produce considerably more ionization by collision before drifting out along the z-axis, ultimately leading to a region of high plasma density and conductivity in the electric node neighbourhood. On the basis of Kapitza's arguments, standing wave frequencies in the neighbourhood of 10^9 cm./sec. would be required to explain the 'observed' fireball sizes of 10–20 cm. Putting this value of ω into condition (10) along with the required electric field strength of 10^6 V./m., it can be seen that the condition for containment in the first region is easily satisfied. In addition, Kapitza has suggested that a fireball is located at the electric field anti-node, whereas our description indicates that the formation process would be expected to take place at the electric node.

Finally, it is suggested that this theory could be tested under laboratory conditions. This could be accomplished by using a standing wave created by a pair of travelling waves fed from opposite sides of the containment region. This is necessary in order to preserve the symmetry about the y–z plane, after the plasma conductivity has reached a point where surface absorption is predominant. Theoretical investigation of genuine three-dimensional plasma containment is at present in progress using three separate standing waves parallel to the x, y and z axes, respectively, the results of which will be published later elsewhere.

I would like to acknowledge many useful and illuminating discussions with Mr. B. Bloch during the initial period of this investigation, and with Drs. R. Wuerker and H. C. Corben during the latter part.

Neutron Diffraction Study of Antiferromagnetic Spin Waves in α-Ferric Oxide

IT has been shown by Elliott and Lowde[1] that spin waves will manifest themselves in the neutron scattering by a crystal as coherent diffuse peaks near the elastic reflexions. In particular, the dispersion relation of the spin waves may be directly obtained from the way the diffuse peak-width Γ changes with $\theta - \theta_B$, the angular missetting of the crystal from the Bragg setting. Such measurements have been done on crystals of iron[2] and magnetite[3], and in both cases a quadratic dispersion law was found.

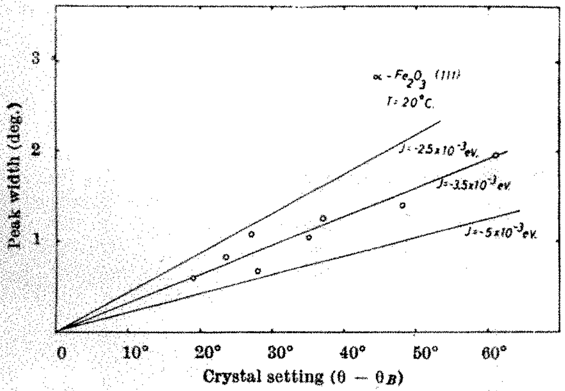

Fig. 1. Diffuse peak width plotted versus angular missetting from Bragg position for (111) reflexion. Straight lines have been calculated for different spin-wave velocities, corresponding to the indicated values of the predominant exchange integral

It may be shown on general grounds that in an antiferromagnet the dispersion law for large wavelengths is linear, so that there is a magnon propagation velocity c_m independent of frequency. As a consequence the relation between Γ and $\theta - \theta_B$ must also be expected to be linear.

Measurements of diffuse peak widths of antiferromagnetic α-Fe_2O_3 (hematite) near the (111) reflexion (rhombohedral indices) indeed show this linear dependence (Fig. 1). From the slope a spin-wave velocity $c_m = 3{\cdot}76 \times 10^6$ cm./sec. is deduced.

A theoretical expression for the spin-wave velocity may be found by solving the secular equation arising from a Heisenberg-type exchange coupling between the spins of the iron atoms, which in hematite belong to four different sub-lattices. The expression contains atomic position co-ordinates and the exchange integrals. The latter have been discussed by Gilleo[4] in terms of super-exchange interactions between iron spins through intervening oxygen atoms. These interactions turn out to be of four types, differing in interatomic distances and angles, and with different values of the exchange integral J. If now, following Gilleo, one ignores all interactions except those belonging to the type with the largest $|J|$, the expression for the spin-wave velocity becomes:

$$c_m = -2^{5/2}\, JSa/\hbar \qquad (1)$$

where S is the iron spin and $a = 5{\cdot}03$ Å. the base of the hexagonal unit cell. The value of c_m is actually slightly dependent on direction of propagation, but this anisotropy is within 4 per cent. Substituting the observed c_m in (1) one finds for the predominant exchange integral $J = -0{\cdot}0035$ eV., the minus sign indicating an antiferromagnetic coupling.

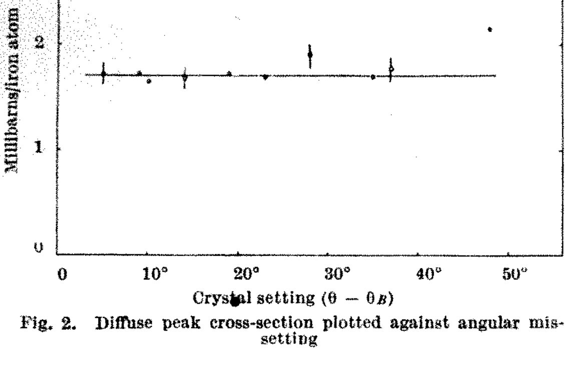

Fig. 2. Diffuse peak cross-section plotted against angular missetting

The value of the exchange integral thus found may be used in a calculation of the diffuse scattering cross-section. Elliott and Lowde[1] have given an expression for the cross-section integrated over the whole diffuse peak for a simple class of antiferromagnets and shown that it is independent of crystal missetting. Their treatment may be generalized to cases including that of hematite for which, with the above value of the exchange integral, it leads to a constant cross-section of 1·4 millibarns per iron atom. The observed values are plotted in Fig. 2 for different angles of misset and show this general behaviour, although with a somewhat higher cross-section value of 1·7 millibarns.

It remains to prove that the observed diffuse peaks are indeed due to antiferromagnetic spin waves and not to lattice vibrations, which also would show a linear dispersion relation. Since the nuclear structure factor of the (111) reflexion is zero, such vibrations could only manifest themselves as magnetic vibrational scattering. To distinguish between the two kinds of scattering one may use their different dependence on the direction of spin alignment. The spin wave cross-section contains a factor $(1 + e_z^2)$, where e_z is the cosine of the angle between the spin direction and the normal to the reflecting plane. The magnetic vibrational scattering, on the other hand, is proportional to $(1 - e_z^2)$, as is the elastic magnetic scattering. This effect has been used in the study of ferromagnetic spin waves, where e_z may easily be varied by an external magnetic field.

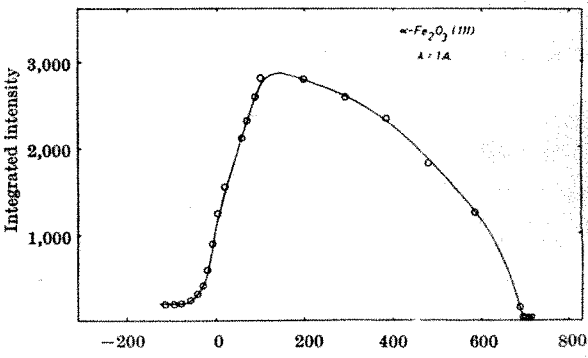

Fig. 3. Temperature variation of the antiferromagnetic (111) Bragg reflexion

In the case of antiferromagnetic spin waves this possibility does not exist. However, in hematite the spin direction is dependent on temperature. Fig. 3 shows the temperature variation of the elastic scattering in the (111) Bragg peak. It is in agreement with the observation of Shull *et al.*[5] that at low temperatures the magnetic moments are pointing along the [111]-direction ($e_z = 1$), whereas at high temperature they are in the (111)-plane ($e_z = 0$). From Fig. 3 and the fact that the inelastic scattering is proportional to absolute temperature, it may be inferred that when the crystal is cooled from 20° C. to − 35° C. the intensities due to spin waves and lattice vibrations should change by + 12 per cent and − 92 per cent respectively. Experimentally an increase of 10 ± 5 per cent was obtained, showing that the diffuse peaks must be of almost pure spin-wave origin.

A complete account of this work will be published elsewhere.

Experiments with Plasma Rings

The use of a coaxial plasma gun with radial magnetic field for the production of magnetized plasma rings was suggested[1] by H. Alfvén in 1958. Experiments with a plasma gun of that type were started in the spring of 1958 and a detailed report is to be published[2]. We present here some new results obtained during continued experiments with a slightly modified plasma gun.

A detailed description of the equipment is given in the previous paper[2]. The main features are described here with reference to Fig. 1, which shows a cross-section of the apparatus. Between the coaxial electrodes of the plasma gun a discharge is set up in hydrogen with a pressure in the range of 0·03–3 torr. The energy, initially stored in the condenser bank of 200 μF., charged to 5–8 kV., is released when the spark gap is triggered by a high-voltage pulse. The electrodynamic force in the plasma pushes the ionized gas towards the muzzle of the gun. Here it encounters a static magnetic field, which is directed radially. The field is maintained by an electromagnet. The central conductor of the gun, which is made of iron, serves as north pole. The outer conductor is of stainless steel, except for the muzzle where an iron plate forms the south pole of the magnet.

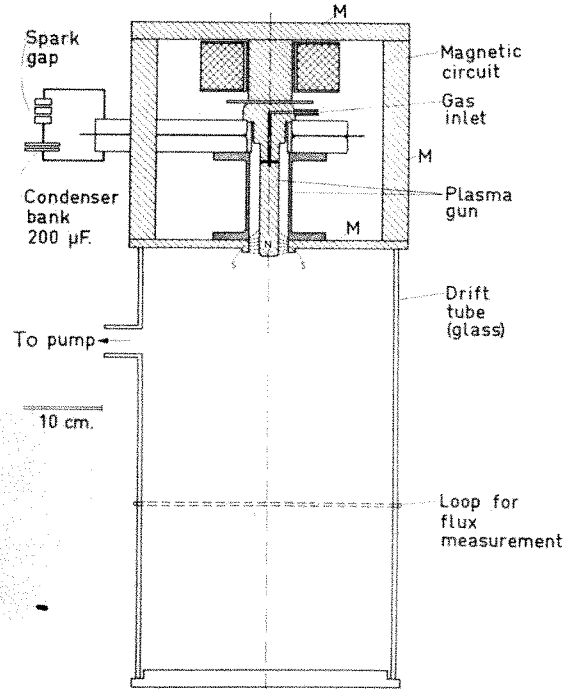

Fig. 1. Cross-section of plasma gun with drift tube

When the accelerated plasma reaches the muzzle it has a high conductivity, so that the magnetic lines of force cannot penetrate it. They are therefore pushed in front of the plasma, down into a drift tube of glass, which is located under the gun. Here a rapid expansion of the plasma towards the glass wall of the tube takes place and a ring of magnetized plasma is formed, through which the stretched field lines of the static field close.

The plasma is studied by means of high-speed photography, using Kerr-cell cameras, and by magnetic measurements. The magnetic flux carried by the plasma is measured by loops around the glass tube connected to integrating resistance-capacity circuits ($R = 10$ k.ohm, $C = 0{\cdot}05$ μF.).

Fig. 2 shows a typical picture of the discharge taken 4 μsec. after the ignition. The luminous front, which probably is due to a shock wave preceding the magnetized plasma, reaches the bottom of the drift tube at about 9 μsec.

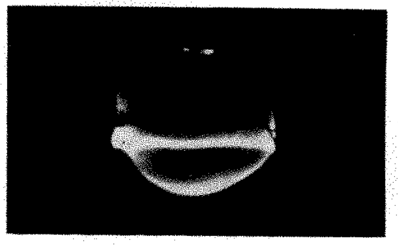

Fig. 2. Kerr-cell photography of the discharge taken 4 μsec. after the ignition

Fig. 3 shows oscillograms of the circuit current and the magnetic flux measured by a loop situated 40 cm. below the muzzle of the gun. The circuit current performs a strongly damped oscillation with a peak value in the first half-cycle of 220 k.amp. and passes through zero 12 μsec. after the ignition. The magnetic flux increases to a maximum, which often appears when the circuit current passes through zero, and then decays approximately exponentially. As the circuit current passes through zero the flux curve is smooth and the direction of the flux through the loop does not change. This indicates that a current continues to circulate in the plasma independently of the circuit current, which is rapidly damped out. Even at 40 μsec. after ignition, a toroidal current is circulating in the plasma.

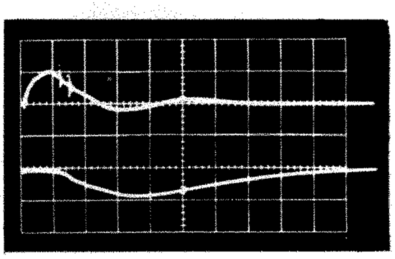

Fig. 3. Oscillogram of the main circuit current (upper curve) and the magnetic flux measured by a loop around the drift tube 40 cm. below the muzzle of the gun and recorded after integration. Time-scale, 5 μsec./div., current scale, 220 k.amp./div. Flux scale, 1 mWb./div. The applied static flux in the plasma gun was 0·47 mWb.

One would expect that the ring-shaped plasma passing the static magnetic field at the muzzle of the gun would conserve the magnetic flux through the central conductor of the gun as a 'poloidal' flux through the hole of the plasma ring formed. Often, however, the flux carried by the plasma is several times greater than the static flux. Whether this can be ascribed to asymmetry in the discharge or whether it depends on some mechanism by which the toroidal flux in the ring is transformed to a 'poloidal' flux is not clear.

CRYSTALLOGRAPHY

Spiral Growth of Colloidal Gold and Moiré Fringe

MANY examples of spiral growth have been reported since Frank[1] introduced the idea of screw dislocation into the general mechanism of crystal growth. Amelinckx[2] has reported growth spirals which appeared on chemically deposited crystals of gold. We also wish to report various growth spirals and related matters recently observed by electron microscopy on lamellar single crystals of gold, prepared colloid-chemically under definite conditions as discussed in previous papers[3]. Brüche and Demny[4] also reported similar patterns on gold crystals and discussed the growth mechanism.

Fig. 1*A* shows a typical example of a lamellar single crystal of colloidal gold having the growth spiral. A small hole exists at the centre of the spiral, from where we can follow the ridge line and, after passing on the outer perimeter of the crystal, we can come back to the initial starting point. The three-dimensional configuration of such a crystal is suggested by Fig. 1*C*, which is an electron micrograph of a specimen replicated by carbon film *in vacuo*, to be in a manner demonstrated by Fig. 1*G*, though slightly exaggerated in its step height. The two spirals on both surfaces of a crystal are nearly symmetrical to each other in most of the present examples. This seems very reasonable as the specimens were grown in a suspension and the condition of the medium was quite the same on both sides of each crystal during growth. Fig. 1*B* shows another example where a rather regular hexagonal loop appeared. We can also observe a small hole as well as the returning loop as indicated by arrows.

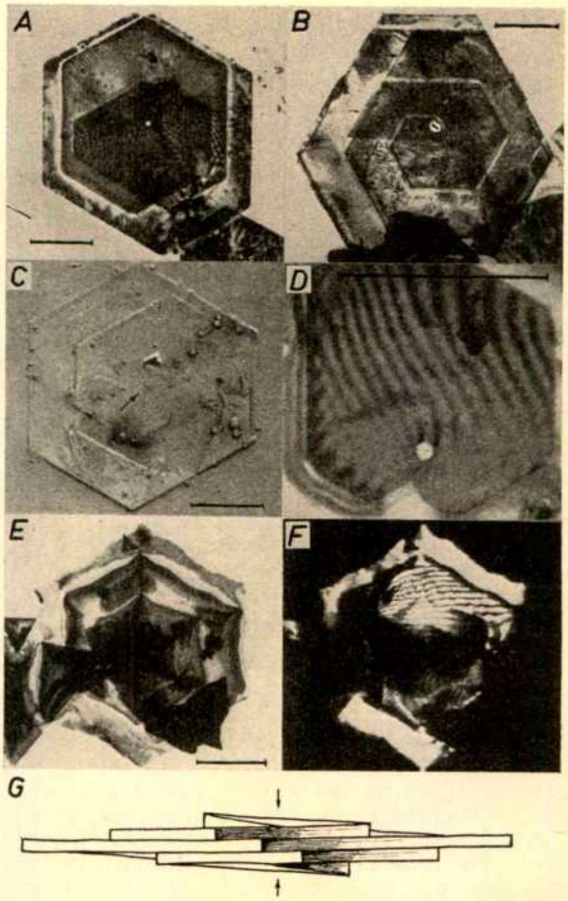

Fig. 1. Electron micrographs and schematic demonstration of single crystals of colloidal gold with growth spirals. Each scale gives 1μ. In Fig. 1*G*, the two arrows show the position of a core of screw dislocations

One of the most outstanding features in the present specimens is that sharp moiré fringes appeared on the growth steps when observed under an electron microscope. Various causes for the moiré fringe have been reported so far[5]. For the present case, we think it reasonable that it is mainly caused by the slight azimuthal rotation of each step, which takes place against another step on which the former one lies and around an axis parallel to the Burgers vector of the screw dislocation, which in turn is normal to the flaky (111) plane of the crystal. Neither considerable separation nor relative inclination of these steps was detected so far as the methods of shadow casting and carbon replica were concerned. We have also taken a set of dark-field images of moiré fringes formed with the electron beam reflected by the lattice plane contained in the region of the crystal where two or more steps were superposed. Fig. 1*F* shows an example of these dark-field images formed with the $(2\bar{2}0)$ reflexion of the crystal, the ordinary electron micrograph of which is shown in Fig. 1*E*. In the dark-field image, there appeared nearly parallel thick moiré fringes, the direction of which is again parallel to $[2\bar{2}0]$ axis of the crystal. This means that they were formed by the interaction of two electron beams reflected respectively by each $(2\bar{2}0)$ plane contained in two superposed steps. The moiré fringe is certainly very sensitive to the slight distortion of the crystal. But when the cause of the fringe is supposed to be attributable only to the slight azimuthal rotation of steps, the angle of rotation α is given by an equation[6]: $\alpha = d_{2\bar{2}0}/D$, where D and $d_{2\bar{2}0}$ are the spacing of the moiré fringe and the interplanar spacing of the $(2\bar{2}0)$ plane. With the set of dark-field images, the angle α has been estimated to be of the order of 2×10^{-3} rad. on an average. Further, it increases roughly linearly from 7×10^{-4} rad. to 4×10^{-3} rad. or to much larger values as the position on the step, where the spacing of the fringe was measured, approaches the centre of the crystal along the spiral step. The application of the same method to another specimen also gave results of the same order for the angle of rotational misorientation.

As for the small hole, we found it on some 60 of about 100 crystals with the spiral marking. Further, it can also be observed in Fig. 1*C* as marked by an arrow, where the original crystal has not suffered from any damage by the electron bombardment. Fig. 1*D* is an enlarged photograph of a hole which is a nearly regular hexagon in shape. Its edge line is oriented in parallel to each ridge line of the step. The growth spiral starts from one apex of the hexagon with round ridge line at the outset. Frank[7] has derived the relationship between the hole diameter (D_0) and the strength of the Burgers vector (b) at the core of the screw dislocation as follows, though slightly modified here:

$$b = 2\pi(S \cdot D_0/G)^{\frac{1}{2}} \quad (1)$$

where S and G are the surface free energy and modulus of rigidity of the material. The hole diameter is distributed over a range of 200–2400 A. and the most probable value is concentrated in a range of 800–1200 A., while the mean value becomes 1020 A. With this value, the strength of the Burgers vector was estimated to be 93–118 A., where $2\cdot76 \times 10^{11}$ dyne/cm.[2] and 600–1,000 erg/cm.[2] were adopted for G and S[8] respectively. On the other hand, we have also estimated the step height to be 109 A. on an average by the shadow-casting method. This is of quite the same order as the strength of Burgers vector above obtained. Thus, if the step height is supposed to correspond directly to the Burgers vector, Frank's theory has been well proved in the present case.

METALLURGY

Decomposition of the Beta Phase in a Copper–Indium Eutectoid Alloy

SOME optical and electron microscopical observations are reported of certain structures resulting from the decomposition of the beta-phase in a copper–indium alloy of approximately eutectoid composition.

The body-centred cubic beta-phase in the copper–indium system undergoes a eutectoid transformation, the eutectoid composition and temperature being approximately 31·4 wt. per cent indium and 574° C. respectively[1,2]. The product of this transformation is pearlitic, consisting of the alpha- and delta-phases. A detailed metallographic investigation of the isothermal transformation characteristics was made by Spencer and Mack[3]. Transformation at approximately 570° C. was found to occur by the formation of nodules of pearlite, resolvable under the optical microscope. The structure of nodules formed during transformation at 547° C. was not resolved optically, but it was reported that it was not homogeneous. Beta-phase, which had not transformed to pearlite, showed a rough-etching or cross-hatched structure when quenched to room temperature.

In the present work an alloy of approximately eutectoid composition was cast into a graphite mould of 3/8 in. diameter. The ingot produced was homogenized for three days at 650° C., and was then cut into disks of 3/32 in. thickness. Disks were quenched from 650° C. into a salt bath at either 565° C. or 547° C., and after being held for selected times at one of these temperatures, they were quenched into cold water. Disks were also quenched directly from 650° C. into cold water. Metallographic preparation of the heat-treated disks included mounting in 'Bakelite', grinding approximately 0·02 in. from the exposed 3/8-in. diameter surface, polishing with diamond dust and electrolytic etching with 1 per cent chromic acid. Examination was made by both optical and electron microscopy, the latter by means of unshadowed 'Formvar' replicas.

Optical microscopical examination (at × 1,400) of specimens partially transformed at 565° and 547° C. showed nodules which were partly resolvable as pearlite: electron microscopical examination of a number of replicas showed a completely pearlitic structure within the nodules. A portion of a nodule is shown in Fig. 1.

The beta-phase, which had not transformed to pearlite, when quenched, generally showed a rough etching appearance under the optical microscope, although there were variations in structure. Examination of replicas revealed the cellular structure illustrated in Fig. 1: a similar structure was shown by replicas taken from a specimen quenched directly from 650° C. into cold water. It may be concluded that it results from the decomposition

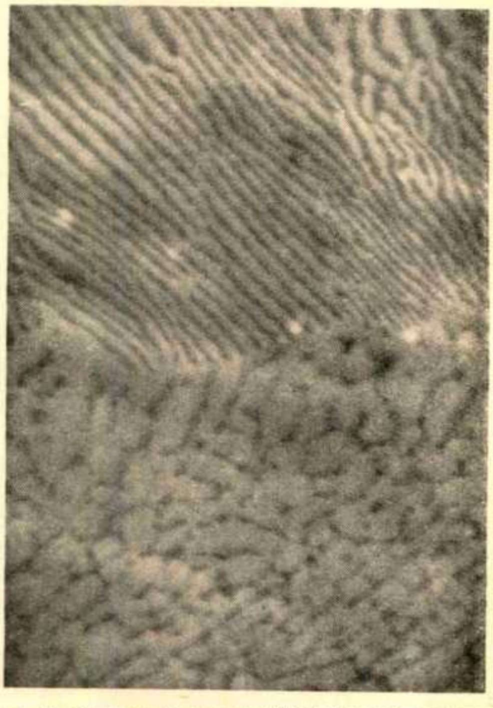

Fig. 1. Replica from specimen partially isothermally transformed at 547° C., showing a portion of a pearlite nodule with the adjacent region of quenched beta-phase (× about 25,000)

of the beta-phase during quenching. The cellular structure bears some resemblance to that observed under the optical microscope in copper–aluminium alloys which have been isothermally treated to produce a mixture of the disordered beta-phase and the ordered beta$_1$-phase (ref. 4 and Thomas, D. L., unpublished work). It is of interest to note that the diffraction pattern of the quenched copper–indium beta-phase has been found to contain lines which indicate a superlattice structure[1]. Thus, it seems possible that the cellular structure may be associated with the occurrence of an ordering reaction on quenching.

Optical microscopy showed that in some regions of the quenched beta-phase, immediately adjacent to the edge of the pearlite nodules, the structure was somewhat columnar in appearance. This effect occurred rather irregularly: where such columnar zones were observed they were commonly approximately 2μ in extent. A similar structural feature was reported by Spencer and Mack[3]. Examination of replicas confirmed that the cellular structure in these zones tended to adopt a columnar form. (This effect is not seen clearly in the particular micrograph shown.) The columnar zones may be associated with the presence of a strain gradient in the beta-phase adjacent to the pearlite nodule interface, the strain being due to volume changes accompanying pearlite formation. During quenching from the transformation temperature, the strain gradient might influence the morphology of the decomposition product of the beta-phase. In the examination of the replicas no interface was detected between the matrix of the cellular structure and one of the phases of the pearlite.

Acknowledgments are made to Mr. H. I. Matthews of the Department of Chemical Engineering, Imperial College, for the use of the Siemens Elmiskop I electron microscope in which the replicas were examined, to Dr. D. L. Thomas for helpful discussions, and to Miss P. Martins for assistance with the photographic work.

Embrittlement of Tungsten and of Molybdenum

A recent paper from this laboratory[1] described the embrittlement of tungsten wire if it be heated in atmospheres containing even traces of ammonia. This work has been extended and has revealed a fact, unobserved in the original study, which furnishes further information which may be helpful in understanding the mechanism. In earlier experiments, the procedure was to heat a length of wire, leaving untreated ends which, since they had not been embrittled, could be clamped in the tensile testing machine without fear of fracture there. The disadvantage of this procedure is that the specimen under test had regions which reached lower temperatures than the central portion, so that any minimum in the embrittlement/treating-temperature curve would not be shown. This aspect was studied in the present series of tests. In these, wire was first annealed so that primary recrystallization was complete[2], and then reheated in nitrogen/hydrogen mixture containing 0·2 per cent ammonia. The whole specimens were then used for the test, neglecting those which broke in the clamps.

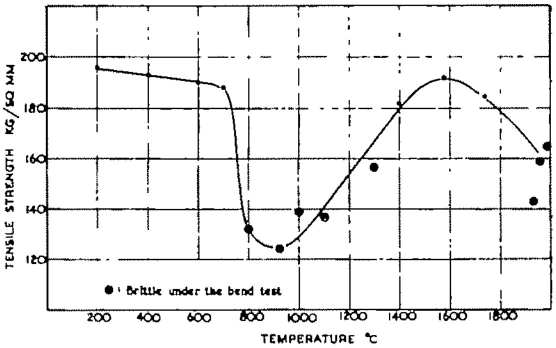

Fig. 1. Effect of heating for 10 min. in 0·2 per cent ammonia on the tensile strength at 20° C. of 180-μ tungsten wire

The results are given graphically in Fig. 1 and show that a minimum embrittlement does indeed occur after heating near 1,600° C.; above this, there is again further embrittlement. Both strength and bend tests were made; the latter were the more subjective but gave clear indications of qualitative changes: specimens which were brittle under this test are also indicated in Fig. 1.

Some recent work which we hope to publish soon has shown that embrittlement of molybdenum wires occurs on heating in presence of elementary nitrogen. While this effect can be important practically, it is quantitatively rather too small to reveal clearly any minimum in the mechanical properties. However, measurements of gas content of treated wires demonstrated that the absorption of nitrogen certainly shows a minimum near 1,300° C., which was not observed in the temperature-range studied by Tury[3], and it may be that there is a parallel mechanism operating for these two similar metals.

CHEMISTRY

Benedict's Solution as a Developer in Carbohydrate Chromatography

While a large number of reagents have been developed for the differentiation of carbohydrates by chromatography, there is still some difficulty in showing reducing sugars in many biological materials. Many of the developers, such as silver nitrate, tend to become easily reduced and to stain the whole paper, the carbohydrates being shown as dark spots on a similarly stained background. This background stain can be removed[1], but the process is both time-consuming and cumbersome.

For many years Benedict's solution has been used to show the presence of reducing sugars in urine, a positive reaction being obtained in solutions containing less than 0·1 per cent glucose. This solution has been used in this laboratory to develop the spots of reducing sugars in chromatograms run to differentiate galactose and glucose in urines containing sugar. The sugars show up as bright orange spots on a pale blue to white background. The intensity of the spot is directly proportional to the concentration of the carbohydrate, and can be used to give a rough estimate of concentration. Two solvents have been used to prepare the chromatograms. These are butanol/acetic acid/water and water-saturated phenol. This last is used in an atmosphere of ammonia. The solutions are allowed to run in descending chromatography for 24 hr.; 0·01 ml. of standard solutions of 1 per cent glucose and galactose are spotted on the base line. The urines are shaken for 20 min. with 'Amberlite *IR*-120' (H) resin and for a further 20 min. with 'Amberlite *IRA*-400' (OH) resin to remove cations and anions which cause tailing of the spots. 0·02 ml. of urine is spotted on the base line and the chromatogram is prepared as described above. The papers are removed from the developing tanks and dried at 80° C. and dipped into or sprayed with Benedict's solution. I find dipping more effective as it gives a more even distribution of the solution. The chromatograms are then developed by drying at 105° C. for 30 min. The spots are fairly permanent if the papers are kept in the dark after evaluation.

This technique has been used successfully for a wide variety of reducing sugars.

A New Silicon Boride, SiB_4

THE existence of compounds in the silicon–boron system has been a subject of conjecture for more than fifty years, since the many studies that have been made have produced negative, inconclusive, or contradicting results. Moissan and Stock[1], in the original work on the system, reported that by fusion of the elements they were able to prepare two compounds, SiB_3 and SiB_6. The SiB_3 was obtained as black rhombic plates with a density of 2·52 gm./cm.^{3}, and the SiB_6 as black irregular crystals with a density of 2·47 gm./cm.^{3}. The borides were reported to have high melting points, high hardness, and to be conductors of electricity, properties which prompted future workers to conduct further investigations.

Attempts by Tone[2] and Brewer[3] were unsuccessful. Studies of ternary systems involving silicon and boron[4] were uncertain regarding the silicon–boron binary, although a possible compound was indicated at about 90 per cent boron. Recently, Samsonov and Latysheva[5] have reported the properties of a tetragonal SiB_3 prepared by a method similar to that of Moissan. Their conclusions regarding the identification of the compound are doubtful, however, as Ormont *et al.*[6] have pointed out. Samsonov and Latysheva also prepared a compound SiB_6, which was studied by Zhuravlev[7], who reported a structure isomorphous with that of CaB_6.

Concurrent with the Russian work, Cline[8] prepared single crystals of SiB_6 and measured many of the physical properties[9]. The crystallographic data[10] indicate that the SiB_6 is orthorhombic and the measured density of 2·43 gm./cm.^{3} is much higher than the value of 2·15 gm./cm.^{3} reported by Zhuravlev for the cubic phase. Further experiments in the system involving the fusion of SiB_6 and silicon yielded a new phase which occurred as rhombs and hexagonal plates. The crystals are reddish-brown under reflected light and have a measured density (sink-float) of 2·44 gm./cm.^{3}. Chemical and spectrographic analyses indicate the formula SiB_4.

Rotation and Weissenberg zero- and upper-level photographs of single crystals of various forms of the SiB_4 indicate a rhombohedral lattice with a = 5·52 A. and α = 69·1°. The corresponding hexagonal cell constants are A = 6·35 A. and C = 12·69 A. There are three molecules of SiB_4 in the rhombohedral unit cell. The probable space groups are $R32$, $R\bar{3}m$, and $R3m$. The density calculated from these data is 2·41 gm./cm.^{3}.

The physical properties of SiB_4 are under investigation, and these properties, as well as the details of the preparation, will be reported at a later date. Intensities are being measured, and a detailed examination of the structure will be made. SiB_4 appears to have some structural features in common with B_4C (ref. 11), and with various forms of elemental boron[12,13], and a comparison of the structures should prove extremely interesting.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

Products of Decomposition of Lead Azide

PREVIOUS work on the decomposition of alpha-lead azide have been performed at temperatures close to its ignition temperature[1,2]. The assumption has been made that the products of such decompositions have been only lead metal and nitrogen gas. The present communication describes the results of a study on the solid material obtained from the low-temperature thermal decomposition of alpha-lead azide.

The material used was a finely divided form of lead azide, prepared in as pure a form as possible. Crystal

Pb_3O_4	Unknown, tetragonal	$a_0=8·80$ $c_0=6·56$	$Z=4$	D^{13}_{4h}, $P4/mbc$ or D^7_{2d}, $P\bar{4}b2$	8·95
$PbCO_3$	Unknown, orthorhombic	$a_0=5·166$ $b_0=8·468$ $c_0=6·146$			

modifiers of all kinds were excluded. Cation impurities such as sodium, calcium, magnesium, iron, silicon and silver totalled less than 0·1 per cent. The mean particle size of the crystals was 7μ.

After thermal decomposition of the azide in fused silica crucibles, the solid residue was examined by X-ray crystallography using copper $K\alpha$-radiation. Both Debye–Scherrer and X-ray diffractograms were obtained. Samples weighing 0·250 gm. were decomposed under ambient pressure and temperatures of 150°, 175° and 200° C.

When the decomposition of lead azide is followed thermogravimetrically at a series of constant temperatures, weight-loss versus time curves like those in Fig. 1 are obtained. These results suggest that at least two phases in the decomposition of alpha-lead azide can be obtained, but the results do not exclude the possibility that the pauses in the curve may be the result of some unknown diffusion process. The results of a decomposition at 175° C., permitted to take place for a period of 230 hr., are shown in Fig. 2. The fact that diffusion is important in the process is evident from a comparison of the co-ordinates of the beginning of the first plateau in this figure and the same curve in Fig. 1.

In order to obtain more information on the nature of the pauses in the decomposition curve, decompositions at 175° C. were carried out for 215 hr. The result in Fig. 2 is representative. The constancy in the loss in weight at the first plateau is noteworthy.

The material which resulted from such decompositions had an intense yellow colour. X-ray diffractogram and Debye-Scherrer patterns were obtained on this material (see Table 1). The reflexions observed have been indexed as primitive cubic and they show excellent agreement between the observed and calculated $\sin^2\theta$ values. In addition, the calculation of the cell parameters suggests that the unit cell is not a perfect cube, since the c_0/a_0 ratio is not exactly 1.

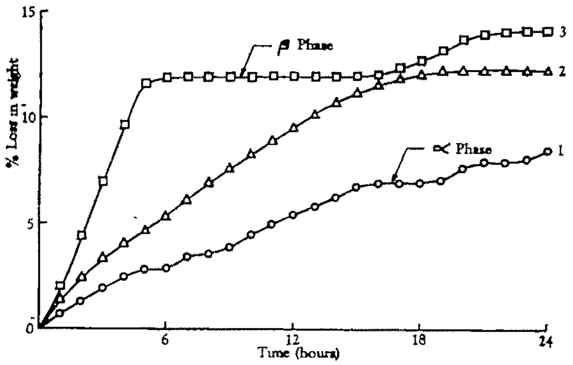

Fig. 1. Thermogravimetric study of decomposition of α-lead azide. (1) Decomposition at 150° C, α-phase ; (2) decomposition at 175° C. ; (3) decomposition at 200°C.

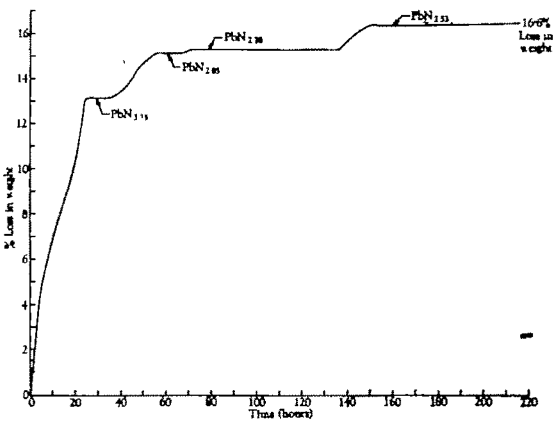

Fig. 2. Decomposition curve of α-lead azide at 175° C.

X-ray analyses of products of intermediate decompositions such as those characterized by the treatments in Fig. 1 suggest that a mixture of phases is present. Relative intensities are presented in Fig. 3 as functions of the reflexion angles. Nitrogen content by chemical analysis of these phases is shown in Table 2. Additional analyses for both lead and nitrogen were performed on a duplicate of sample 4 of this table. The lead was precipitated as lead sulphate and nitrogen determined by Dumas's method. The results in duplicate are :

Lead 81·98 per cent	Nitrogen 16·53 per cent
82 03	16·65
av. 82·00	av. 16·59

The material balance shows that oxygen can be present in the decomposition product only to the extent of 1·4 per cent if at all.

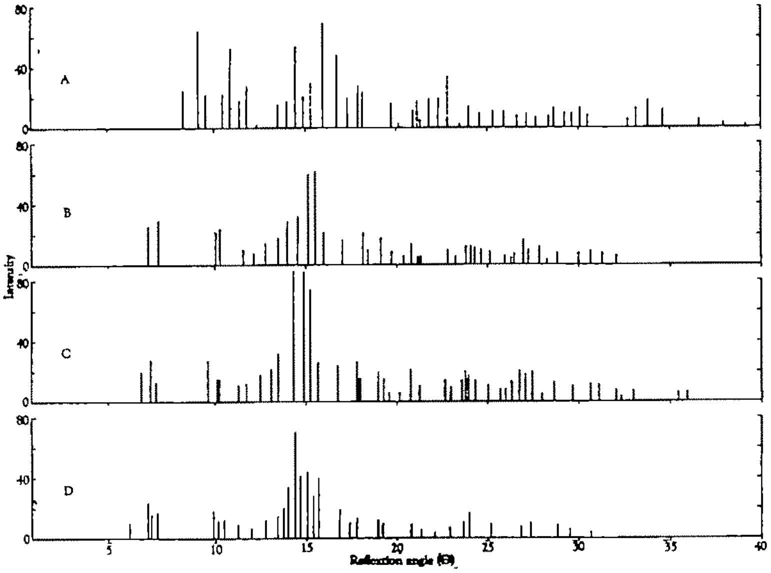

Fig. 3. Comparison of X-ray reflexions of untreated and heat-treated α-lead azide (*A*) Untreated α-$Pb(N_3)_2$; (*B*) $PbN_{4\cdot33}$ α-$Pb(N_3)_2$ heated for 24 hr. at 150° C. ; (*C*) $PbN_{3\cdot33}$ α-$Pb(N_3)_2$ heated for 24 hr. at 175° C. ; (*D*) $PbN_{3\cdot09}$ α-$Pb(N_3)_2$ heated for 24 hr. at 200° C

These results, plus an examination of data for probable materials which might result from heating alpha-lead azide in air as compiled in Table 3, suggests that under these conditions alpha-lead azide decomposes in a step-wise fashion through several distinct phases having varied lead to nitrogen ratios. The clarity of the diffractograms has been rewarding, and the very sharp lines exhibited have given no reason for assuming disorder in the structures. Work to confirm these results in more detail is in progress.

We thank Mr. J. J. Campisi for taking the X-ray diffractograms and Debye–Scherrer patterns : and Mr. C. Campbell for the thermogravimetric work.

Molecular Structure of Neopentane

WE have recently studied the molecular structure of pivalonitrile[1], $(CH_3)_3CCN$, and have found the central C—C bond to be 1·46 ± 0·02 A. The carbon skeleton in pivalonitrile is similar to that in neopentane and, therefore, a comparison of the C—C distance in neopentane with the central C—C distance in pivalonitrile should be a measure of the effect of an adjacent triple bond on the C—C distance. It was also considered interesting to see if the C—C distance in neopentane would be longer than in ethane due possibly to steric repulsions. The only parameters available for neopentane were from the early visual work of Pauling and Brockway[2] and a re-investigation of the structure of this molecule seemed timely.

The sample used for the diffraction photographs was obtained from Phillips Petroleum Co. It was characterized as Phillips's research grade with a mole per cent purity of 99·92. Electron diffraction photographs were taken, using an r^3 sector, at camera distances of 25·10 cm. and 10·19 cm. employing electrons of wave-length 0·05452 A. and Kodak lantern slide plates. Exposure times of 10 sec. for the long camera distance and 30–45 sec. for the short camera distance were used. Three patterns at the short camera distance and two at the long camera distance were chosen for the visual measurement of ring diameters and estimation of intensities. The visual results from the sectored plates extended from $q = 17$ to $q = 100$.

A radial distribution curve was calculated from the sector-visual intensity data[3]. The data for the range $q = 0$ to $q = 17$ were supplied from a theoretical curve[3].

The radial distribution curve (Fig. 1) shows three peaks and a few shoulders. The peak at 1·09 A. corresponds to the bonded C—H distance and the one at 1·54 A. corresponds to the bonded C—C distance The peak at 2·51 A. corresponds to the non-bonded C···C distance. The shoulder at 2·17 A. is attributed to the short non-bonded C···H distance. The shoulder at about 2·75 A. is due to the intermediate non-bonded C···H distance and the peak at 3·46 A. corresponds to the long non-bonded C···H distance. It is interesting to note that there is a small shoulder at about 1·8 A. which is caused by the short non-bonded H···H distance. The amplitudes of vibration of a few atom pairs were estimated by Karles's method[4,5]. The radial distribution results are summarized in Table 1.

Table 1. RESULTS FROM THE RADIAL DISTRIBUTION CURVE

Distance	Peak position (A.)	Δr_{ij}	Area[c]	$\frac{nZ_iZ_j}{r_{ij}}$
C—H	$1\cdot08_9$	0 075	90	88
C—C	$1\cdot54_4$	0·05	100	100
C·· H (short)	$2\cdot16_4$[a]	—		
C·· C	$2\ 51_4$[b]	0·08	201	206
C·· H (intermediate)	—	—		
C·· H (long)	$3\cdot45_8$	$0\ 20_8$	26	28

[a] This is consistent with a CCC angle of 109° 28′.
[b] Appears as a shoulder at about 2·75 A.
[c] Areas of the peaks were approximated to bell shapes.

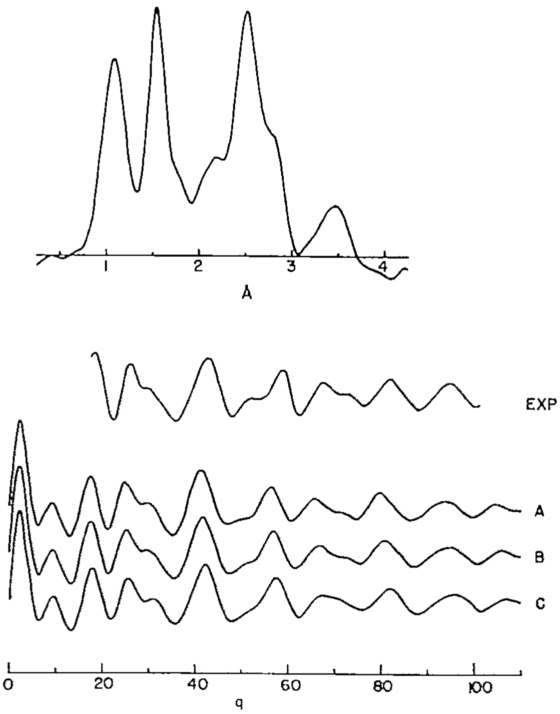

Fig. 1. The radial distribution curve and the experimental and theoretical intensity curves for neopentane

A correlation procedure has also been carried out. Six theoretical models with bonded C—C distances of 1·48 A. (*E*), 1·50 A. (*D*), 1·52 A. (*C*), 1·54 A. (*B*), 1·56 A. (*A*), and 1·58 A. (*AA*) were calculated. The bonded C—H distance and the CCC angle were maintained constant at 1·09 A. and 109·5° respectively. The hydrogen atoms were kept as far as possible from each other. Of these models all are qualitatively acceptable with the possible exception of the 1·48 A. model which is a borderline case. A model calculated with a bonded C—C distance of 1·54 A. assuming free rotation was found completely unacceptable. The quantitative electron diffraction results for the acceptable models are given in Table 2 and the parameters from the acceptable models are summarized in Table 3.

Table 3. PARAMETERS FROM ACCEPTABLE MODELS

	AA	*A*	*B*	*C*	*D*	*E*
C—H	1 06$_3$	1·07$_8$	1 09$_0$	1 10$_8$	1 11$_7$	1·13$_8$
C—C	1 54$_1$	1·54$_8$	1·54$_8$	1·53$_8$	1 53$_8$	1·53$_3$

The final parameters of the molecule from this study are:

$$\text{C—C} = 1{\cdot}54 \pm 0{\cdot}01 \text{ A.}$$
$$\angle\text{CCC} = 109{\cdot}5 \pm 1°$$

No attempt was made to determine the C—H distance as any such determination would result in an uncertainty of at least ±0·05 A.

It is interesting to note that the C—C distance in neopentane is equal to the value of 1·54 A., which has usually been accepted as the normal C—C single-bond distance. Within the estimated uncertainty, this distance is also consistent with the value of 1·533 A. proposed by Bartell[6] as the normal C—C single bond distance in straight-chain hydrocarbons. The interatomic distances obtained in this investigation are in agreement with those obtained earlier by Pauling and Brockway[2], but the present work is regarded as more accurate.

We wish to thank the Phillips Petroleum Co. for providing the sample of neopentane. This communication contains material from the master's thesis of one of us (C. L.).

Crystallization of Non-Racemic Mixtures of the Isomers of Serine

IF the enantiomorph (unlabelled) of a labelled isomer is available, the maximum contamination of the particular labelled compound by its enantiomorph may be assessed by a crystallization method. Repeated crystallization of a mixture of enantiomorphs in which one (unlabelled) is present in large excess of the other (labelled) would be expected to lead to a purification of the more abundant isomer; hence, the presence of isotope in the purified abundant isomer should represent contamination of the labelled antipode. Thus, when enzymatically prepared[1,2] D-glutamic acid-2-^{14}C was diluted about 2,000-fold with carrier L-glutamic acid and the mixture crystallized, via the hydrochloride and the free amino-acid, to constant specific activity, it could be calculated that the maximum amount of contaminant L-glutamic acid-2-^{14}C was less than 1 per cent[3].

We have resolved DL-serine-3-^{14}C (obtained from Nuclear-Chicago Corp.) by the selective enzymatic hydrolysis of the N-chloroacetyl derivative[3]. To estimate the purity of the labelled D- and L-serine samples, the latter were diluted about 2,000-fold with carrier D- or L-serine and subjected to repeated recrystallization from water or ethanol–water mixtures. Aliquots of the various crystalline products obtained were assayed for carbon-14[4]. The results are presented in Table 1. Surprisingly, when the labelled serine isomers were diluted with their respective antipodes (^{14}L + D, or ^{14}D + L), successive

† Corrected for dilution with carrier. Therefore, the results give the relative specific activities of each precipitate.

‡ Per cent (by weight) of original mixture recovered.

§ Per cent (by weight) of previous crystallization recovered.

recrystallization led to an increase in specific activity, the increase being approximately inversely proportional to the recovery (by weight) during a given crystallization. Thus, in the case of ^{14}D + L (Series *A*, seventh recrystallization), 4·2 per cent of the original serine contained 49 per cent of the original carbon-14, an enrichment of isotope of more than eleven-fold. Repeated recrystallization of ^{14}L + L or of ^{14}D + D gave products of fairly constant specific activity except when the recovery of serine was low, in which case the specific activities fell markedly.

These unusual results can be explained only by assuming that the carrier D- and L-serine used were contaminated with several per cent of their respective enantiomorphs, and that during recrystallization the contaminants were preferentially precipitated. Apparently, the DL-component of each mixture was almost quantitatively precipitated under conditions in which the L- or D-isomer was quite soluble. The lesser solubility of DL-serine as compared with D- or L-serine[5] is in accord with this hypothesis, although the difference in solubilities does not afford a complete explanation of the results.

Optical rotations, determined spectrophotometrically, support the above hypothesis. (Optical rotations were determined by using a Keston polarimeter attachment to a Beckman Model *DU* spectrophotometer (Standard Polarimeter Co., Hackensack, New Jersey, U.S.A.). All rotation measurements were made at 589 mμ using 5 *N* hydrochloric acid as solvent (temperature 24–27° C.)). The specific rotations of the carrier D- and L-serine were, respectively, − 11·8 ± 1° and + 12·8 ± 1°. Specific rotations ranging from 0 to 4·60 ± 3° were obtained on the final precipitates of the two serine recrystallization series (Table 1). Greenstein *et al.*[2] have reported specific rotations for pure serine isomers (in 5 *N* hydrochloric acid) of about 15°.

In contrast to the results with serine, recrystallization of the *p*-toluenesulphonyl derivatives gave a purification of the more abundant isomer. Thus, in the case of ^{14}D + L (series *B* and *C*), recrystallization as serine yielded a precipitate the specific activity of which was 1,000 times that obtained after recrystallizing the *p*-tosyl derivative of the same serine sample. Results obtained with the *p*-tosyl derivatives prove that the D- and L-serine-3-^{14}C samples contained no more than about 1 per cent of their respective enantiomorphs.

The technique described above for assessing a slight degree of racemization in labelled D- or L-compounds appears to be a valid and valuable one. However, in instances where the racemate is less soluble than the D- or L-isomers, large errors are possible if the isomers used for dilution are not pure. In this connexion we found that a single crystallization of D-serine-3-^{14}C, diluted 5,000-fold with L-serine of higher optical purity ($[\alpha]^{27}_{D}$ = + 14·6 ± 1°) than that originally used, yielded results similar to those obtained with the *p*-tosyl derivatives.

The results also illustrate that recrystallization of an optical isomer contaminated with only a few per cent of its enantiomorph may lead to a concentration rather than removal of the contaminant.

We wish to acknowledge the financial support of the U.S. Public Health Service (No. *SF*-14) and the U.S. Atomic Energy Commission (Contract No. *AT*-(40–1) 2003).

A New Route to 1-Substituted Pyrazole-4-Carboxylic Acids

1-PHENYLPYRAZOLE-4-CARBOXYLIC acid has been hitherto most successfully synthesized by chloromethylation of 1-phenylpyrazole and subsequent oxidation of the 4-chloromethyl-1-phenylpyrazole[1], or by hydrolysis of the 4-cyano derivative formed from the anti-oxime of 4-formyl-1-phenylpyrazole[2]. A synthesis of this acid has now been achieved by the hydrolysis of 4-cyano-1-phenylpyrazole formed by a Sandmeyer type reaction from 1-phenylpyrazole-4-diazonium chloride. Replacement of the pyrazole-4-diazonium group by nitrile has hitherto been unsuccessful[3,6].

The starting material, 4-nitro-1-phenylpyrazole, was prepared in quantitative yield by the method of Hill and Torrey[4]. Reduction by hydrazine catalysed by Raney nickel[5] yielded 4-amino-1-phenylpyrazole (97 per cent). This reagent we found to be an excellent reductant for 4-nitropyrazoles. The following pyrazoles: 4-nitro-1-2′-quinolyl-, 1-2′-benzthiazolyl-4-nitro-, and 4-nitro-1-2-5-trimethyl- have also been reduced to the corresponding amines in yields varying between 87 and 100 per cent (unpublished work).

4-Amino-1-phenylpyrazole was diazotized and added to a potassium cuprocyanide solution at 80°.

Ether extraction gave a 56 per cent yield of 4-cyano-1-phenylpyrazole, m.p. 94–95° (Lit.[3] 95°). Found: C, 70·8; H, 4·4; N, 24·8. Calc. for $C_{10}H_7N_3$: C, 71·1; H, 4·1; N, 24·8 per cent. A quantitative yield of 1-phenylpyrazole-4-carboxylic acid, m.p. 221–222°, was obtained on hydrochloric acid hydrolysis of the 4-cyanopyrazole.

The overall yield of 1-phenylpyrazole-4-carboxylic acid by this synthesis is greater than 50 per cent and the route should provide easy access to other 1-substituted pyrazole-4-carboxylic acids.

There is but one reference in the literature to a similar substitution by this method of a pyrazole-4-diazonium group by halogen and the yields were poor[6]. We have found that, utilizing cupric salts as catalysts at elevated temperatures, halogen can be introduced in good yield, for example, 1-phenylpyrazole-4-diazonium bromide gives 4-bromo-1-phenylpyrazole in 86 per cent yield.

BIOCHEMISTRY

3 : 3′-Diamidinocarbanilide: a New Drug Active against Babesial Infections

Quinuronium sulphate[1] is the commonly employed treatment for British bovine redwater and a single injection of 1 mgm. of this drug per kgm. of body-weight is effective in a high proportion of cases. But quinuronium sulphate has the disadvantage that even in therapeutic doses it produces toxic effects associated with parasympathetic stimulation. The diamidines, phenamidine and pentamidine, as their di-isethionates, and Berenil are well tolerated and are also used for the treatment of bovine babesiasis, but they are less active than quinuronium sulphate.

During the search for a new drug which would be at least as effective as quinuronium sulphate but without its toxic effects, a large number of compounds has been screened for activity against *Babesia rodhaini* in mice, and the most promising of these were tested against *Babesia divergens* in splenectomized calves. One of the best of these was M and B 5062*A* — 3 : 3′ - diamidinocarbanilide di-isethionate, which was active against *B. divergens* in calves and produced none of the toxic effects associated with quinuronium sulphate. This activity of the 3 : 3′-diamidine was unexpected because of the inactivity of the corresponding 4 : 4′-diamidine. 3 : 3′-Diamidinocarbanilide di-isethionate[2] was prepared, among other methods, by the usual Pinner reaction on the corresponding dinitrile. It is a white, crystalline, anhydrous solid, m.p. 209° C. (decomposing at 256° C.) (found: N, 15·1; S, 11·6 per cent. $C_{15}H_{16}ON_6,2C_2H_6O_4S$ requires: N, 15·3; S, 11·7 per cent), and is approximately 100 per cent w/v soluble in water.

The acute toxicity (*LD*50) of M. and B. 5062*A* in mice was found to be 120 mgm./kgm. subcutaneously compared with 8 mgm./kgm. for quinuronium sulphate, while a comparison of the two compounds in non-infected, splenectomized calves after subcutaneous injection at a site behind the shoulder showed that the maximum tolerated dose of M. and B. 5062*A* was greater than 40 mgm./kgm., and that of quinuronium sulphate less than 4 mgm./kgm. There were no obvious symptoms of toxicity in the calves that received this dose of M. and B. 5062*A*. During the therapeutic activity tests two calves developed mild ataxia which lasted for about 3 hr. after treatment with a dose of 40 mgm./kgm.; otherwise no symptoms of systemic toxicity were observed.

In the therapeutic activity tests, seventeen calves infected, after splenectomy, with *B. divergens* were treated subcutaneously with M. and B. 5062*A* at doses between 3 and 40 mgm./kgm. body-weight. With all doses the intensity of the parasitæmia was reduced within 24 hr. and complete clearance was obtained within three days. In all the calves treated with 5 mgm./kgm. or higher doses, the hæmoglobinuria was cleared in 24 hr.

Further details, including a report on field investigations, will be published in due course.

We thank Mr. T. G. Mitchell for much technical assistance in the experiments with *B. rodhaini* and *B. divergens*.

Metabolism of 1-^{14}C Lignoceric Acid in the Rat

Lignoceric acid, the straight-chain, saturated C_{24} fatty acid, occurs in sphingolipids in amide linkage with the amino-alcohol sphingosine[1,2]. It has not been found in the ester linkages of neutral fat or glycerophosphatides, and very little information is available on its metabolism. In the work reported here, lignoceric acid labelled with ^{14}C carboxyl was administered to rats and its metabolic fate studied.

Lignoceric acid was isolated from peanut oil and converted to 1-^{14}C lignoceric acid, via 1-^{14}C tricosyl cyanide (modification of Anker's method for synthesis of myristic acid[3]). Contrary to the fatty acids of 18 carbon atoms or less, lignoceric acid did not form a soluble complex with serum albumin. Paper electrophoresis of a mixture of 1-^{14}C lignoceric acid and serum albumin (0·5–1 equivalent of the acid per equivalent of albumin) showed that the radioactive fatty acid did not migrate with the albumin but remained at the point of origin. 1-^{14}C lignoceric acid was therefore injected as a neutralized aqueous suspension into the tail vein of rats; the various organs were isolated and extracted with a 2:1 chloroform methanol mixture. Respiratory carbon dioxide labelled with carbon-14 was collected in some experiments, and, in others, the livers were removed, dried and extracted successively with acetone, petroleum ether and ethanol. The acetone and petroleum

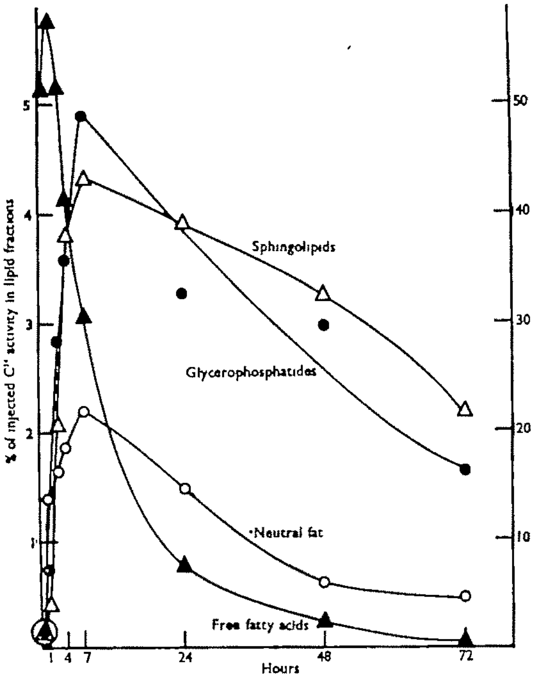

Fig. 1. Incorporation of 1-^{14}C lignoceric acid into rat liver lipids. 6 µmoles of 1-^{14}C lignoceric acid (94,000 c.p.m.) were given by intravenous injection to rats. At the specified times, the animals were, killed and the liver lipids fractionated as described in the text

ether extracts were combined and the lipids separated into a petroleum ether and acetone soluble fraction (that is, neutral fat and free fatty acids) and a petroleum ether soluble, acetone insoluble fraction (that is, glycerophosphatides)[4]. Sphingolipids were isolated from the ethanol extract. The neutral fat was separated from the free fatty acids by passing through a magnesia-'Celite' column[4]. The glycerophosphatides were purified by repeated precipitations of their petroleum ether solutions with acetone and the sphingolipids by repeated precipitations of their ethanol solutions with acetone.

Within 15 min. after injection, about 99 per cent of the 1-^{14}C lignoceric acid was removed from the blood. More than 50 per cent of the injected radioactivity was found in the liver. Small amounts were present in the lungs and spleen ; no radioactivity was found in the brain and only traces in the adipose tissue. A similar pattern of distribution was observed after 24 hr.

About 20 per cent of the radioactivity of the administered 1-^{14}C lignoceric acid appeared in the respiratory labelled carbon dioxide in 7 hr. After an initial lag of about 30 min., the rate of production of labelled carbon dioxide increased, reached a maximum 2 hr. after injection and then declined slowly.

Contrary to the findings with the lower fatty acids[5,6], feeding a stock diet, a diet rich in carbohydrates or fasting, did not influence the formation of labelled carbon dioxide from 1-^{14}C lignoceric acid.

Both the rate of incorporation of 1-^{14}C lignoceric acid into liver lipids and the turnover-rate of these lipids (Fig. 1) were much lower than with palmitic acid[7]. Also, contrary to palmitic acid[7], a large fraction (about 50 per cent) of the injected lignoceric acid was found as the free acid in the liver ; even after 24 hr. about 8 per cent of the free fatty acid was still present in the liver.

A considerable part of the lignoceric acid incorporated into liver lipids was found in the sphingolipids (Fig. 1). However, 1-^{14}C lignoceric acid was also found in the neutral fat and glycerophosphatides. This esterification of lignoceric acid, which has not been observed previously, might be due to the presence, in unphysiological amounts, of free lignoceric acid in the liver.

The results presented indicate that while 1-^{14}C lignoceric acid was metabolized by the rat, its metabolic behaviour differed from that of lower fatty acids, such as palmitic acid. Experiments with tissue preparations are in progress to elucidate further the above findings.

Ribonucleases in Takadiastase

THE existence of a thermostable ribonuclease in commercial takadiastase was first pointed by Kuninaka[1]. We found afterwards by zone-electrophoresis the existence of at least three enzymes attacking ribonucleic acid in takadiastase: one of them is more active at *p*H 7·5 and the others are more active at *p*H 4·5 [2].

Two of the enzymes, which we named ribonuclease T_1 and ribonuclease T_2, were partially purified by the following procedure: heat treatment, ammonium sulphate fractionation, adsorption to and elution from calcium phosphate gel. Ribonuclease T_1 was further purified by eliminating impurities with active charcoal, and T_2 by chromatography with *DEAE*-cellulose[2,3]. The preparations thus obtained of ribonuclease T_1 and T_2 were shown to be practically homogeneous in zone-electrophoresis.

Ribonuclease T_1 split the internucleotide bonds between 3′-guanylic acid groups and 5′-hydroxyl groups of the adjacent nucleotides with the intermediary formation of guanosine-2′,3′-cyclic phosphate[3–5].

This mechanism was deduced from the following experimental evidence: (1) ribonuclease T_1 digesting yeast ribonucleic acid produces exclusively 3′-guanylic acid (*Gp*) as mononucleotide; (2) the terminal residue of oligonucleotides produced was shown to be exclusively guanylic acid; (3) as an intermediate of the reaction, guanosine-2′,3′-cyclic phosphate ($G_{\text{cyclic P}}$) was obtained with good yield, and it was further hydrolysed to 3′-guanylic acid :

$$
\begin{gathered}
—XpGpXp—XpGpGpXp— \\
\downarrow \text{RNase } T_1 \\
—XpG_{\text{cyclic P}} + Xp—XpG_{\text{cyclic P}} + G_{\text{cyclic P}} + Xp— \\
\downarrow \text{RNase } T_1 \\
—XpGp + Xp—XpGp + Gp + Xp—
\end{gathered}
$$

G, guanosine
X, other nucleosides

Similar experiments were undertaken with ribonuclease T_2, and in this case it was proved that it splits the internucleotide bonds between 3′-adenylic acid groups and 5′-hydroxyl groups of the adjacent nucleotides. However, contrary to the reaction catalysed by ribonuclease T_1, cyclic mononucleotides were not readily obtained[3].

The specificity of ribonuclease T_1 and T_2 is indeed just complementary to that of the well-known pancreatic ribonuclease (ribonuclease 1), at least the main component, component A, which catalyses the cleavage of internucleotide bonds between the 3′-pyrimidine nucleotide groups and the 5′-hydroxyl groups of adjacent nucleotides[6].

Some properties of ribonuclease T_1 and T_2 together with ribonuclease 1 are summarized in Table 1.

Table 1. PROPERTIES OF RIBONUCLEASE T_1, T_2 AND I

	Optimum *p*H	Specificity	Activation and inhibition				References
			Mg++ Ca++	Cu++	EDTA	ICH₂COOH	
T_1	7·5	*Gp*	inhibited	inhibited	activated	activated	(2) (4) (5)
T_2	4·5	*Ap*	inhibited	strongly inhibited	activated	activated	(2) (3)
I	7·6	*Up* *Cp*	activated	inhibited		inhibited	(6)

Ribonuclease T_1 and T_2 catalyse the synthesis of oligonucleotides from guanosine-2′,3′-cyclic phosphate ($G_{\text{cyclic P}}$)[7,8] and adenosine-2′,3′-cyclic phosphate ($A_{\text{cyclic P}}$)[8] respectively. For example, ribonuclease T_1 catalyses the synthesis of guanylyluridine, guanylylcytidine, guanylyladenosine and guanylylguanosine from cyclic guanylic acid and uridine, cytidine, adenosine and guanosine respectively. It catalyses also the polymerization of cyclic guanylic acids. Part of the products are poly- or relatively large oligo-guanylic acids, because they are non-dialysable and give the colour reaction by gallocyanine[9].

$$G_{\text{cyclic P}} + U = GpU \qquad G_{\text{cyclic P}} + C = GpC$$
$$G_{\text{cyclic P}} + A = GpA \qquad G_{\text{cyclic P}} + G = GpG$$
$$nG_{\text{cyclic P}} = GpGpGp\text{—}Gp.$$

Similar reactions were also observed with ribonuclease T_2. These synthetic reactions are analogous to those of oligopyrimidine nucleotides catalysed by ribonuclease I[10]. The generality of such synthetic reactions by certain ribonucleases suggests the possibility of the participation of these enzymes in the intracellular synthesis or reformation of specific ribonucleic acids.

Preparation of oligo- and poly-guanylic acids and cyclic nucleotides by ribonuclease T_1. As mentioned above, ribonuclease T_1 catalyses the polymerization of cyclic guanylic acid. By fractionation on *ECTEOLA*-cellulose column, oligo- and poly-guanylic acids were obtained[8].

K. Sato-Asano and Y. Fujii showed that deaminated yeast ribonucleic acid could be hydrolysed by ribonuclease T_1[11]. By controlled digestion of yeast ribonucleic acid and deaminated yeast ribonucleic acid, guanosine-2′,3′-cyclic phosphate and two new compounds, inosine-2′,3′-cyclic phosphate and xanthosine-2′,3′-cyclic phosphate, were obtained respectively with good yields[12].

Abolition of the streptolysin-forming activity of ribonucleic acid. An interesting biological effect of ribonucleic acid was disclosed by Okamoto's finding that yeast ribonucleic acid stimulated the synthesis of streptolysin ('Streptolysin S') by hæmolytic streptococci[13]. The streptolysin-forming activity of ribonucleic acid was rapidly decreased by ribonuclease T_1[14]. This finding is consistent with the observations which suggest that the activity depends on the consecutive sequence of guanylic acids[15].

Possibility of the determination of nucleotide distribution in ribonucleic acid. As various proteinases have contributed to the determination of amino-acids sequence in protein, ribonucleases with different specificity may be useful for the elucidation of the structure of ribonucleic acid.

In Table 2 the hydrolysis of a hypothetical polynucleotide by ribonuclease I, T_1 and T_2 is presented. By combining the information about the nucleotide sequences of hydrolysis products, the complete nucleotide sequence may be deduced[8].

Table 2. HYDROLYSIS OF A HYPOTHETICAL POLYNUCLEOTIDE

	G–A–U–C–C–G–A–A–G–G–C–U–U–G–A–C–U
Ribonuclease I	*G–A–U C C G–A–A–G–G–C U U G–A–C U*
Ribonuclease T_1	*G A–U–C–C–G A–A–G G C–U–U–G A–C–U*
Ribonuclease T_2	*G–A U–C–C–G–A A G–G–C–U–U–G–A C–U*

Native ribonucleic acids so far obtained are too large and may be a mixture of polynucleotides with different nucleotide sequences. However, by analysing mono- and oligo-nucleotides produced by the three ribonucleases and applying simple probability calculation, we may be able to determine how the nucleotide sequence deviates from that of random distribution. The information thus obtained may be an indication for the specificity of nucleotide distribution of the ribonucleic acid.

In conclusion, we believe that ribonuclease T_1 and T_2 will prove useful for studies of nucleic acids and related problems.

The expense of this study was defrayed in part by a grant from the Ministry of Education of Japan.

Occurrence of Riboflavin in Sturgeon Skin

LOOMEIFER[1] has reported the presence of a yellow fluorescent pigment in elastin and has commented upon the views of Szent-Györgyi[2] on the function of riboflavin-5-phosphate in metabolism as an energy transmitter. Blair and Graham[3] found riboflavin to be present in the skin of green snakes. These reports of fluorescent materials associated with connective tissues, which are metabolically relatively inert, have prompted this note of the occurrence of riboflavin in sturgeon skin. These observations form part of a survey on non-teleostean fish collagen.

The skin of a young (7 kgm.) sturgeon (*Acipenser sturio*) was mechanically freed from muscle and scales and heated in water, adjusted with acetic acid to *p*H 4·5, for 3 hr. at 60° C. in the dark. Approximately 80 per cent of the collagen was converted into gelatin, which, as a 5·6 per cent (w/v) solution, gave the physical properties shown in Table 1, and compared with gelatins from isinglass (*Acipenser huso huso*), shark skin (*Selachus maximus*) and cod swim-bladder (*Gadus morrhua*) which were prepared under similar conditions.

Table 1. PROPERTIES OF FISH GELATINS

	gelatin 5·6% (w/v)	
	rigidity dynes/cm.[3] at 10° C.	viscosity cp. at 40° C.
Sturgeon skin	25,000	5·2
Isinglass	60,000	5 8
Shark skin	45,000	4·3
Cod swim-bladder	*c.* 100	4·0

The gelatin solution from the sturgeon skin was unusual in that it was associated with a yellow pigment showing a strong green fluorescence. The fluorescence was destroyed by sunlight. The absorption spectrum of this gelatin, plotted between 380 and 580 mμ, was found to be similar (Fig. 1) to that for an acid-processed pig skin gelatin to which riboflavin had been added. In addition, when the sturgeon skin gelatin was irradiated with an ultraviolet source for 30 min. and the absorption curve plotted, it was found that the hump shown by curve *D*, Fig. 1, had been removed so as to resemble curve *B*. The plot of the differences in absorption between the irradiated and non-irradiated forms is shown in Fig. 2. The maximum at approximately 455 mμ corresponds to the maximum given by riboflavin. It seems likely, therefore, that riboflavin is the colour component of this sturgeon gelatin.

It remains to be seen whether the presence of riboflavin in sturgeon skin is a pigmentation phenomenon or whether it is a metabolic factor involved in the laying down of collagen in a young animal.

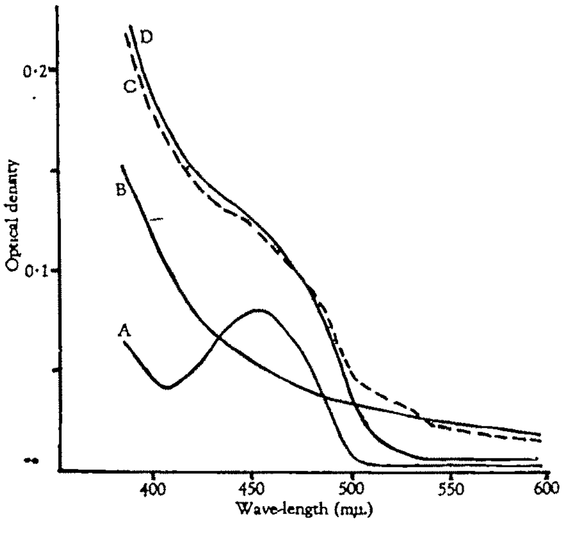

Fig. 1. Absorption spectra: curve *A*, riboflavin; curve *B*, pig skin gelatin; curve *C*, pig skin gelatin with added riboflavin; curve *D*, sturgeon skin gelatin

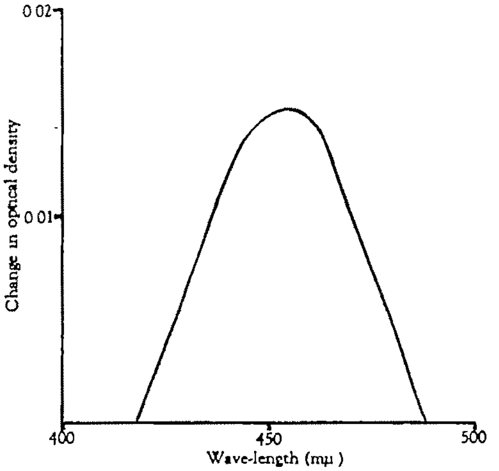

Fig. 2. Changes in the optical densities of sturgeon skin gelatin occurring after ultra-violet irradiation

I am most grateful to H.M. The Queen and to the Comptroller of Supplies, Buckingham Palace, for arranging the gift of a sturgeon.

Properties and Solubility of Phenolase in Isolated Chloroplasts

THE phenolase complex in green plant tissue has often been assumed to be present only in the chloroplasts[1]; but it has recently been shown that in sugar beet leaf phenolase is also present in the mitochondria and 'soluble' fraction of homogenates. The enzyme associated with chloroplasts was shown to be characterized by a high cresolase activity, the ratio of catecholase to cresolase activities being close to unity. Disruption of such chloroplasts with distilled water increases both activities by 35 per cent[2].

In order to examine further the chloroplast phenolase of sugar beet leaf, we have attempted to extract it by a number of methods. The preparation of chloroplasts and manometric determination of enzymic activities have been described previously[3]. Chloroplasts were macerated by hand in an all-glass homogenizer with the solutions described in Table 1, left to stand for the time indicated and then separated by centrifugation for 5 min. at 3,700*g*. All the preparations were carried out in a cold room at − 1° C.; the acetone had previously been cooled to − 20° C.

The treatments with either sodium deoxycholate or acetone (Table 1, *a*–*e*) increased the total amount of phenolase activity compared with that in whole chloroplasts. The increases ranged from two and a half-fold with acetone (*c*) to six-fold with acetone and sodium deoxycholate (*e*). With the exception of treatment (*a*), all the extracts (*b*–*e*) had increased catecholase/cresolase ratios when compared with the original whole chloroplasts. The first treatment (*a*)

* This shows the solution in which the chloroplasts were macerated, and the time during which they were left at 0° C. before centrifuging.

† $\dfrac{\text{Total activity in extract}}{\text{Total activity in extract + T.A. in residue}} \times 100$

‡ $\dfrac{\text{Total activity in extract + T.A. in residue}}{\text{Original total activity of whole chloroplasts}}$

§ Both the sodium deoxycholate and digitonin were dissolved in *M*/15 phosphate buffer at the *p*H's indicated above.

¶ Chloroplasts rapidly macerated with acetone and then centrifuged. Total time of contact therefore 5¼ min. Acetone residue then extracted as indicated above.

yielded the highest amount of activity in the extract (~ 70 per cent).

Digitonin (Table 1) also extracted about 70 per cent of the total phenolase, but in this case the extract had a greatly increased catecholase/cresolase ratio, and the residue a decreased one; furthermore, there was no increase in activity after the treatment. The activation of chloroplast phenolase by acetone and deoxycholate, on one hand, and the lack of activation by digitonin, on the other, may be comparable phenomena to those observed by Kenten[3] for the latent phenolase of bean leaf. He found that the latent phenolase is activated by anionic but not by non-ionic wetting agents.

It is important to note that with the treatments used, not all the phenolase could be extracted from the chloroplasts. This finding suggests that the enzyme is either tightly bound to, or forms part of, some structure in the sugar beet chloroplast. Phenolase may, therefore, have a specific function in the chloroplast, possibly associated with its high cresolase activity.

We thank Mr. G. E. Russell, Plant Breeding Institute, Trumpington, for generous supplies of sugar beet leaves and Dr. R. Hill and Dr. T. Swain for helpful discussions.

Transmethylation in *Anodonta cygnea*

IN a previous survey of the distribution in Nature of betaine-homocysteine-methyl-transferases, these enzymes were found in the livers of all vertebrate animals investigated[1,2]. They could not be detected in any of a number of lower animals examined. The search for the enzymes has since continued, which has led to the discovery of a betaine–homocysteine–methyl-transferase in a member of the Mollusca, the pond mussel *Anodonta cygnea*. The work on which this observation is based will be briefly reported here.

The mussels were harvested in Lake Mälaren and transported in lake water to the laboratory. The livers were excised and homogenized in ice-cold phosphate buffer (0·05 *M*, *p*H 7·8) in a Potter–Elvehjem homogenizer. Methyl donors and homocysteine were added to the homogenate to give incubation mixtures having the compositions shown in Tables 1 and 2. Controls without additions, or containing only betaine or homocysteine, were also prepared. The amount of methionine formed after incubation at 37° C. for 2–4 hr. was estimated microbiologically[3] and in some instances also chemically[4].

Table 1. FORMATION OF METHIONINE BY HOMOGENATES OF *Anodonta* LIVER IN THE PRESENCE OF THE COMPOUNDS LISTED

Additions	Methionine formed (μgm./mgm. nitrogen per hr.)
None	1·8
0·025 *M* DL-homocysteine	2·9
0·1 *M* betaine	1·6
0·1 *M* betaine + 0·025 *M* homocysteine	8·3
0·1 *M* choline + 0·025 *M* homocysteine	3·0
0·1 *M* betaine + 0·025 *M* homocysteine + 0·1 *M* choline	8·3
0·1 *M* betaine + 0·025 *M* homocysteine + 0·1 *M* dimethylglycine	3·8

Table 2. EFFECT OF VARIOUS METHYL DONORS
All incubation mixtures contained 0·025 *M* DL-homocysteine

Methyl donor (0·05 *M*)	Relative activity (per cent)
Betaine	100
Betaine methyl ester	100
Betaine amide	0

Carboxymethyl-methyldiethyl-ammonium chloride	5
Carboxymethyl-triethyl-ammonium chloride*	0*
Dimethylacetothetin†	380
Dimethylpropiothetin†	300
N-trimethyltaurine (taurobetaine)	0

* No ethionine was formed.

† No attempt was made to find optimal conditions for transmethylation from these compounds.

As can be seen from Table 1, the incubation mixtures containing betaine and homocysteine had a higher methionine content at the end of the incubation period than the controls. The presence of homocysteine alone consistently caused the formation of a small but significant amount of methionine, which suggests that the liver of *Anodonta* contains a donor of methyl groups. The addition of choline and homocysteine did not stimulate the synthesis of more methionine than did the addition of homocysteine alone. This indicates that choline is not in itself a methyl donor and that the choline oxidase activity of this tissue is low. The enzyme system causing the formation of methionine from betaine and homocysteine remained in the supernatant fluid after centrifuging homogenates prepared in 0·25 *M* sucrose at 105,000*g* for 60 min. Incubation of the supernatant fluid with ^{14}C-methyl betaine and homocysteine gave rise to radioactive compounds with the same R_F-values as methionine and dimethylglycine in three different solvent systems. The apparent *p*H-optimum of the reaction was near 8·5, which is higher than the optima observed for the methyl transferases of vertebrate livers.

The results in Table 1 also show that dimethylglycine, but not choline, inhibited the synthesis of methionine. Table 2 shows that the methyl donor requirement of the transferase of *Anodonta* liver could be satisfied to a greater or lesser extent by certain betaine derivatives and thetins. It is of interest to notice that the methyl ester of betaine possessed full donor activity, whereas the amide was completely inactive. The length of the carbon chain between the carboxyl group and the nitrogen is apparently of vital importance, as neither propio- nor butyro-betaine was able to serve as donor of methyl groups. Carnitine was also inactive. Both aceto- and propio-thetin, on the other hand, were excellent methyl donors. The introduction of a methyl group in the α-position relative to the carboxyl group in betaine decreased the activity, probably due to steric hindrance.

Replacement of one or two of the N-methyl groups of betaine with ethyl groups gave compounds having approximately 35 and 5 per cent of the activity of unsubstituted betaine. No evidence of ethyl group transfer from these compounds or from 'triethylbetaine' was obtained.

N-trimethyltaurine (taurobetaine), recently isolated from a species of Porifera by Ackermann *et al.*[5], was also tested as a methyl donor but did not seem to have this property. Nor did it act as an inhibitor of the enzyme.

Betaine–homocysteine–methyl-transferase activity could not be detected in any other organ than the liver of *Anodonta cygnea*.

I wish to thank Profs. F. Challenger, G. S. Fraenkel, D. Ackermann and Dr. B. Wickberg for supplying samples of acetothetin, carnitine, 'natural' taurobetaine and synthetic taurobetaine, respectively, and Mr. Nils Walde for help with the synthesis of the other compounds tested as methyl donors. The financial support of the Swedish Medical Research Council and the Knut and Alice Wallenberg Foundation is also gratefully acknowledged.

Separation of the Hypnotic Potentiating Principles from the Essential Oil of *Acorus calamus* L. of Indian Origin by Liquid–Gas Chromatography

THE sedative potentiating activity of the essential oil of *Acorus calamus* L. of Indian and European origin has been reported[1].

It is the purpose of this communication to describe the isolation and identification of the active principle or principles responsible for the above-mentioned pharmacological activity from the essential oil of *Acorus calamus* L. of Indian origin.

In our investigations the volatile oil distilled from *Acorus calamus* L. of Indian origin by Fritzsche Bros., Inc., New York, was used, and liquid–gas chromatography was employed as a technique for the isolation of the individual components. The essential oil was first freed from phenols, acids and carboxylic compounds by the usual chemical procedures[2]. Subsequent to this the majority of other polar components were removed by passing the partly purified oil (75 gm.) through a silica-gel column (40 gm., 100–200 mesh, dried at 110° C.).

The purified oil (50–200 µl.), which exhibited the same pharmacological activity as the crude oil, was injected into an 'Aerograph' liquid–gas chromatography unit (Wilkens Instrument and Research, Inc., Walnut-Creek, California). The column consisted of a 10-ft. length of 1/4-in. stainless steel tubing packed with Johns–Mansville 'Chromosorb' (35–80 mesh) coated with 'Ucon' polar substrate in a ratio 75/25 by weight. The oven temperature was 205° C. and dried helium was used as carrier gas with a flow-rate of 64 ml. per min. measured at the outlet of the apparatus. These conditions were used throughout. Under these conditions the essential oil of *Acorus calamus* L. of Indian origin separated into a number of fractions (Fig. 1).

Four fractions were collected and tested pharmacologically. Fractions U_1 and U_2 appeared to be inactive pharmacologically. Fractions U_3 and U_4 potentiated the activity of pentabarbitone sodium. Fraction U_4 proved to be asarone, 1,2,4-trimethoxy-5-propenylbenzene (calculated C per cent 69·23; H per cent 7·69; found C per cent 69·13, H per

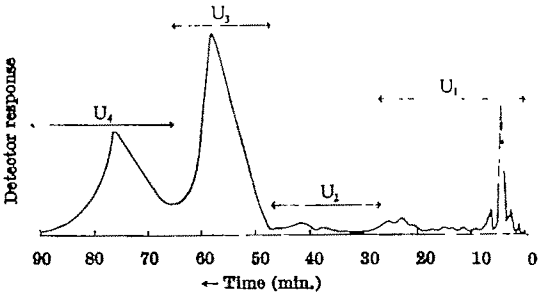

Fig. 1. Liquid-gas chromatogram of 200 μl. essential oil of *Acorus calamus* L. of Indian origin after removing the oxygenated compounds. Column, 'Ucon' polar on 'Chromosorb' 10-ft. × ¼ in. Temperature, 205° C. Flow, 64 ml. of helium per min.

cent 7·43). The compound melts at 58–61° C. (recorded m.p. 61° C.[3]): its picrate melts at 80° C. (recorded m.p. 81–82° C.[4]). Fraction U_3 is a colourless and odourless oil, which when treated with inorganic acids gives the same parasarone as fraction U_4 gives with similar treatment (m.p. 195–200° C., recorded m.p. for parasarone 202–203° C.[5]). After reduction with hydrogen in the presence of palladium charcoal a colourless oil was formed, the retention time of which, under the above-mentioned conditions, is identical with the retention time of the oil derived from fraction U_4 hydrogenated in the same manner. (The hydrogen consumed in both cases is about 1 mole calculated for trimethoxypropenylbenzene.) The ultra-violet spectra of fractions U_3 and U_4 are almost identical. (Absorbancy maxima occur at 253 mμ and 302 mμ.) From these results it can be concluded that the fraction U_3 and fraction U_4 are in *cis–trans* isomeric relationship, as was published earlier[6]—the fraction U_3 proved to be β-asarone.

It is to be noted that re-injection of fraction U_4, which was shown to be asarone, resulted in the appearance of two peaks on the chromatogram (U_4 and U_{4I}, Fig. 2, solid line). After several re-injections of the collected asarone, derived from the previous injection, fraction U_{4I} appeared repeatedly and the ratio between the two peaks did not change.

From these observations the conclusion may be drawn that the second peak is not due to a contamination but probably is due to a compound formed during the liquid–gas chromatography procedure. This assumption is supported by another experiment. When pure asarone was kept at 200° C. in a sealed tube under nitrogen for 24 hr., and the mixture formed injected into the column, two peaks, fraction U_4 and fraction U_{4I}, also appeared on the chromatogram, but the ratio between the peaks changed significantly compared to the former experiment when pure asarone was injected into the column. The quantity of fraction U_{4I} increased markedly (Fig. 2, dotted line).

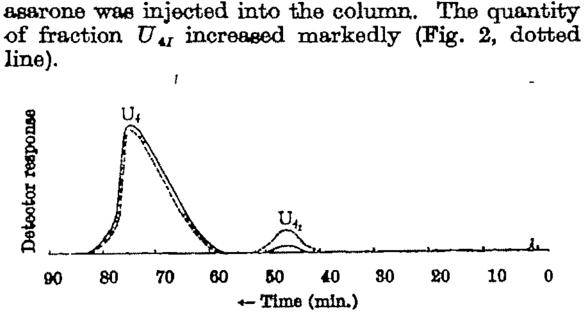

Fig. 2. Liquid–gas chromatogram of 100 μgm. U_4 (solid line) and 100 μgm. U_4 after keeping 24 hr. at 200° C. in a sealed tube under nitrogen (dotted line). Column, 'Ucon' polar on 'Chromosorb' 10 ft. × ¼ in. Temperature, 205° C. Flow, 64 ml. helium per min.

A small amount (about 150 μl.) of the fraction U_{4I} was collected and purified by liquid–gas chromatography. It is a light yellowish odourless oil, which does not crystallize even at temperatures of − 50° C. On treating with inorganic acid a colourless amorphous solid forms, which is different from parasarone. Its ultra-violet spectrum is almost identical with that of asarone and β-asarone. (Absorbancy maximum at 253 mμ and 302 mμ.) The pharmacological activity is different from asarone and β-asarone, in that it possesses not only hypnotic potentiation activity but also sedative activity.

Further studies are in progress to determine the chemical structure of this latter compound. Details of the pharmacological action and chemical nature of these compounds will be published elsewhere.

Methylglyoxal Formation from Aminoacetone by Ox Plasma

IT was previously reported[1–3] that washed suspensions of *Staphylococcus aureus* synthesize aminoacetone from either threonine or glycine and the new aminoketone was isolated in crystalline form. Laver *et al.*[4] and Kikuchi *et al.*[5] have independently demonstrated the formation of aminoacetone by preparations of red blood cells and have shown that the system which forms δ-aminolævulinic acid is responsible for this activity.

I suggested recently[3] that aminoacetone might be involved in a metabolic cycle and postulated that it undergoes deamination to yield methylglyoxal. The present communication is concerned with this aspect of the metabolism of aminoacetone.

Preliminary studies showed that tissue slices of either rat liver or kidney catalysed a slow disappearance of the aminoketone, but so far it has not been possible to demonstrate an unequivocal enzymic attack on aminoacetone using cell-free extracts of these tissues. It was, however, observed that citrated ox plasma catalysed a rapid oxidation of aminoacetone to yield a product which, unlike aminoacetone, gave an immediate reaction with dinitrophenylhydrazine. The enzyme has been purified approximately tenfold by ammonium sulphate fractionation and this purified preparation was used for the subsequent work described here.

To identify the product of aminoacetone oxidation an incubation mixture containing 400 μmoles of aminoacetone (in a final volume of 120 ml.), plasma enzyme, crystalline catalase and phosphate buffer, *p*H 6·2, was shaken for 3 hr. at 37°. At the end of this period the aminoacetone had completely disap-

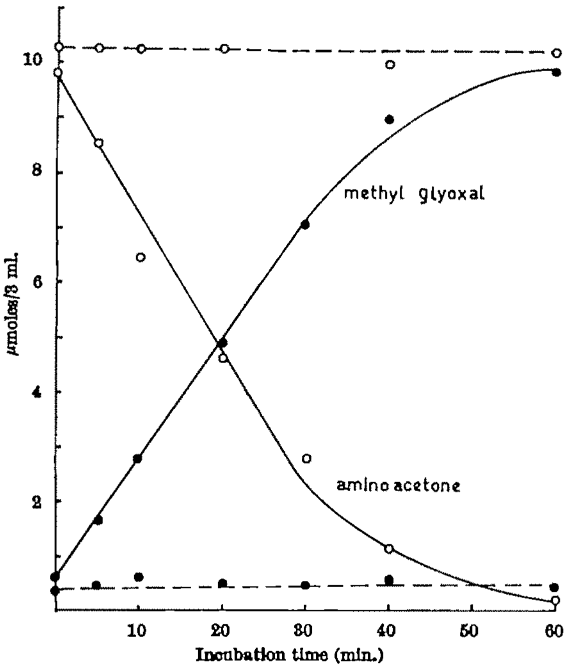

Fig. 1. Broken lines represent a control experiment in which the enzyme was boiled before addition

peared. After deproteinization the extract was passed through a column of 'Zeokarb 225' (*H* form) to remove any amino compounds, and the product isolated from the effluent as the dinitrophenylosazone. A control incubation mixture which was identical, except that aminoacetone was added after incubation, gave no osazone when treated in the same way. The product was recrystallized as orange-red needles from anisole. Yield: 0·056 gm., m.p. 298–300° (decomp.) (lit.[6] 295° decomp.; 299–300° decomp.). Found: C, 41·9; H, 2·9; N, 25·8. Calc. for methylglyoxal 2:4-dinitrophenylosazone, $C_{15}H_{12}N_8O_8$: C, 41·7; H, 2·8; N, 25·9 per cent. The isolated product gave the blue-violet colour in alkali characteristic of methylglyoxaldinitrophenylosazone. The identification of the product of aminoacetone oxidation as methyglyoxal was further confirmed by the observation that a partially purified ox heart glyoxalase preparation caused its disappearance, and this was dependent on the addition of glutathione.

Fig. 1 shows the progress of the enzymic reaction with time. Methylglyoxal was formed in amounts equivalent to the aminoacetone disappearing, and no reaction occurred when the enzyme was previously boiled. The aminoketone was quantitatively oxidized and no diminution in the reaction-rate took place until the substrate concentration was reduced to less than 10^{-3} *M*. In these experiments methylglyoxal was measured by a colorimetric method based on that described for pyruvate assay[7].

Manometric studies have shown that in the presence of added catalase, one atom of oxygen was taken up for each molecule of aminoacetone oxidized. In the absence of catalase, the initial rate of oxygen consumption was approximately double that in its presence, but the rate fell off rapidly. However, oxygen uptakes significantly in excess of one atom per molecule of aminoacetone present have been obtained under these conditions, indicating that the following reaction occurs:

$$CH_3.CO.CH_2NH_2 + O_2 \rightarrow CH_3.CO.CHO + H_2O_2 + NH_3$$

The purified enzyme used in these experiments contained amine oxidase activity[8] as measured by benzylamine oxidation and it is possible that aminoacetone oxidation is catalysed by this enzyme.

The present results are believed to be the first unequivocal demonstration of methylglyoxal formation from a substrate known to occur naturally and as such suggest a function for the glyoxalase enzyme system. The distribution of the aminoacetone oxidizing system in mammalian tissues is now being investigated.

Although all the steps of the postulated cycle[3] have now been shown to occur in suitable preparations, it nevertheless remains to be established whether the reactions take place as a metabolic pathway in living organisms. Experiments to this end are being undertaken.

I am indebted to Prof. A. H. Ennor for his stimulating interest in this work and for many helpful discussions.

Evidence for the Hexose Monophosphate Pathway for Glucose Metabolism in Human Pancreatic β-Cells

THE level of glucose in the blood perfusing the islets of Langerhans is thought to regulate the secretion of insulin by the β-cells[1]. At present nothing is known about the mechanism of this regulation or even about the way in which the β-cells metabolize glucose. Studies designed to provide information about these problems are hampered by the fact that the pancreatic islets are rather diffusely scattered throughout the entire exocrine portion of the gland and comprise only about 2 per cent of the total pancreatic tissue[2]. Even if one were successful in obtaining islet tissue free of exocrine pancreas, the β-cells represent only 60–90 per cent of the total cell population[3]. However, in humans there are insulin-producing tumours of the pancreas which are usually composed of only β-cells and such tissue does afford an opportunity to study β-cell metabolism. A ratio greater than unity for the amount of carbon dioxide labelled with carbon-14 derived from glucose-1-^{14}C as compared to that from glucose-6-^{14}C has been taken as evidence for the existence of the hexose monophosphate pathway in the tissue under study[4]. The present report concerns studies using a β-cell tumour and indicates that there is an active hexose monophosphate pathway in these cells (this patient was studied through the kindness of the National Institute of Neurological Diseases and Blindness, National Institutes of Health, Bethesda, Md.). It is realized that the metabolism in these benign tumours may not be completely analogous to that of β-cells in normal islets.

Paired tissue slices weighing approximately 100 mgm. were incubated in glucose–Krebs Ringer bicarbonate buffer containing 0·5 μc. glucose-1-^{14}C or glucose-6-^{14}C and a final glucose concentration of 250 mgm. per cent. Incubations were done at 37° C. on a Dubnoff shaker under an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide for 90 min. In addition, some flasks also contained 0·01 mgm. of alloxan since this substance is known to destroy β-cells[5]. At the end of the incubation, hyamine was put in the centre well and the carbon dioxide was liberated from the incubation mixture by the addition of 10 *N* sulphuric acid. The hyamine containing labelled carbon dioxide was counted in a liquid scintillation counter using 0·4 per cent diphenyloxazole in toluene as the phosphor. Two control flasks without tissue but with 0·5 μc. glucose-1-^{14}C and glucose-6-^{14}C respectively were also included. For comparison similar experiments were done using rat hemidiaphragm, which is known to be devoid of the hexose monophosphate pathway[4].

The results are shown in Table 1. In slices from the β-cell tumour there were five to six times as many counts in labelled carbon dioxide when glucose-1-^{14}C was present as compared to glucose-6-^{14}C, indicating that the hexose monophosphate pathway was operative. In contrast, the radioactivity in labelled carbon dioxide from the rat muscle was approximately the same for both glucose-1-^{14}C and glucose-6-^{14}C. In addition, there did not appear to be any significant decrease in conversion of glucose to carbon dioxide in the presence of alloxan.

Table 1. CONVERSION OF GLUCOSE-1-^{14}C AND GLUCOSE-6-^{14}C TO $^{14}CO_2$ BY HUMAN PANCREATIC β-CELLS AND RAT HEMIDIAPHRAGM

Tissue	Counts/min./gm. in $^{14}CO_2$ from Glucose-1-^{14}C		Glucose-6-^{14}C	
β-cells	16,030	(2)	3,885	(2)
β-cells + alloxan	19,225	(2)	3,650	(2)
Rat hemidiaphragm	9,325	(2)	9,070	(2)

Number of determinations in parentheses

The full significance of the presence of an active hexose monophosphate pathway in β-cells cannot be ascertained although one can make some interesting inferences. Recently, the role of this pathway as a source of reduced triphosphopyridine nucleotide has been emphasized, and it has been suggested that it is of importance in many synthetic processes[6]. It has also been reported that stimulation of this pathway can lead to increased protein synthesis[7]. It is quite conceivable that the synthesis and secretion of insulin, which appears to be regulated in some manner by the blood glucose concentration, are thus facilitated by glucose metabolized via the hexose monophosphate pathway.

The finding that alloxan had no apparent effect on the conversion of glucose to carbon dioxide was somewhat unexpected. It may be that the dose of alloxan was too small or that alloxan, itself, is not toxic but that a metabolic product in the body is responsible for the β-cell damage. Other possibilities are that alloxan requires more than the 90-min. incubation period to disrupt β-cell metabolism or that the effects of this drug are not exerted on glucose catabolism but rather on some other essential cellular process[8]. It is also conceivable that β-cells in islet cell tumours are more resistant to alloxan than β-cells in normal islets.

ANIMAL PHYSIOLOGY

A Peanut Factor for Hæmostasis in Hæmophilia

IT is known that there are unpredictable apparent remissions of clinical symptoms enjoyed by hæmophiliacs; but these remissions have not been correlated with any influences such as time of year, food eaten, weather conditions, other diseases, or physical condition of the patient. The lack of 'antihæmophilic factor' associated with classic hæmophilia has been attributed[1] to a hypothetical block during the metabolic synthesis of the factor resulting from the action of the mutant gene of hæmophilia, such as occurs in the nutritional mutants of *Neurospora* and in eye pigment development in certain mutants of *Drosophila*[2]. In the cases of *Neurospora* and *Drosophila*, and other organisms studied, the addition of the substances the synthesis of which is blocked genetically results in normal metabolism. If this is the case in hæmophilia, it may be possible to supply, by mouth or injection, the unavailable material necessary for normal production of the hæmostatic substance lacking in hæmophiliacs. However, the few instances of success of various supplements, such as vitamins E and B_{12}, X-rays, and œstrogen, have not been confirmed[3-7].

One of us (H. B. B.) suffers from antihæmophilic factor hæmophilia, and in the past has been able to perform his duties with the help of periodic transfusions of fresh blood or infusions of lyophilized plasma following a hæmophilic attack. Various foods likely to overcome the hypothetic metabolic block by furnishing substances in the antihæmophilic factor pathway have been ingested in large daily quantities (blood pudding, liver, raw milk, eggs) without causing any reduction in severity of the disease. In May 1957, however, there seemed to have occurred a rapid loss, following consumption of a large handful of roasted peanuts, of tenderness (indicating a stoppage of bleeding) in a knee with an active hæmatoma. This loss in tenderness occurred without other therapy.

Since then, peanuts in all available forms (commercial peanut-butter, roasted, or raw peanuts) have been ingested on the appearance of each hæmophilic attack, and in each instance the clinical symptoms were relieved in one or two days.

During a period of more than two years, when peanuts, peanut flour, or a concentrate prepared from peanut flour has been in use, it was necessary only once to use lyophilized plasma to control a bleeding episode. This bleeding occurred in the lower pharynx, making ingestion impossible. Whenever peanut products are avoided, the tendency to bleed recurs, but yields to re-establishment of peanut regimen.

The relief of clinical symptoms brought about by peanut material is not correlated with reduction of capillary blood clotting time measured in glass capillary tubes, or of venous blood clotting time measured by the Lee–White method. No other attempts were made to measure any possible effects *in vitro*. In spite of the unreliability of the capillary tube method of measuring clotting time, the deepest punctures during periods of ingestion of peanut material have always healed without special treatment or rebleeding. The same normal healing has occurred in all cases of skin wounds occurring during the ingestion of peanut material.

Efforts have been made to concentrate the active factor. Peanut flour, prepared on extracting lightly roasted peanuts with hexane, and the crude extracted oil were each tested separately. The hæmostatic effect seems to be confined to the flour. It was found by Boudreaux, and by a second antihæmophilic factor hæmophiliac volunteer (aged fifty-three), that clinical symptoms are apparently relieved in one or two days with doses of 180 gm. of the flour per day. A third volunteer (aged five) has had relief from bleeding while taking flour or screw-pressed extracted meals. Boudreaux is at present effectively using screw-pressed extracted meal as a prophylactic.

The active factor is removed from peanut flour by extraction with 90 per cent ethyl alcohol. The residue was ineffective in relieving clinical symptoms, whereas the alcohol-extracted material was apparently effective in one or two days in doses of 14 gm. (the equivalent of 1 lb. of peanuts) per day, as indicated in tests carried out by Boudreaux and a fourth volunteer (aged eighteen). In the case of the fourth hæmophiliac, relief was obtained with the concentrate in two days, when he had failed to respond to 9 plasma infusions administered over a period of 3 weeks. A finger which was badly bruised in a motor-car door during the period of ingestion of peanut concentrate required no special treatment. During another bleeding episode, 12 infusions of fresh plasma given to this fourth volunteer in 10 days did not stop bleeding from the kidneys. Plasma was discontinued, and two days later the alcohol-extracted material was administered orally in 5-gm. quantities every 6 hr. No blood appeared in the urine on the second day. The volunteer was discharged from the hospital three days later.

It is unlikely that enough antihæmophilic factor was produced on ingestion of the concentrate to cause clinical relief, but enough to affect 'clotting time'. Enhanced thrombocyte action alone may be sufficient for hæmostasis without fibrin production[8]. Another possibility is that the peanut factor hastens capillary healing or improves capillary integrity without effect on blood hæmostatic reactions[9]. Current tests on hamsters in our laboratory suggest that vasoconstriction is enhanced by ingestion of the concentrate.

It is hoped that these limited observations will incite the interest of medical research to help determine the general occurrence of this phenomenon. Meanwhile, efforts are continuing to concentrate and identify the active factor, and to develop a bioassay on laboratory animals.

Distribution of Tryptophan in the Brain

IT is well established that the central nervous system of vertebrates contains a substance which is biologically and chromatographically indistinguishable from 5-hydroxytryptamine. The tissues richest in 5-hydroxytryptamine are the diencephalon and mesencephalon, with little or none in the cerebellum or white matter. In the course of paper chromatographic studies on the distribution of 5-hydroxytryptamine in the brain of vertebrates, a second indole substance was noted and afterwards identified as the amino-acid, tryptophan. The distribution of tryptophan did not always follow closely that of 5-hydroxytryptamine, and this result may be of importance since it is believed that 5-hydroxytryptamine is formed by the decarboxylation of 5-hydroxytryptophan, an amino-acid formed from tryptophan.

Acetone extracts of tissues from freshly killed animals were subjected to paper chromatography in four solvents: (1) 8 per cent (w/v) sodium chloride solution, (2) *iso*propanol/ammonia/water (20 : 1 : 2), (3) *n*-propanol/water (3 : 1), (4) *n*-butanol/acetic acid/water (4 : 1 : 5). The identity of tryptophan was established chemically by its R_F values in the different solvents and by its colour reactions with ninhydrin, Ehrlich's reagent, Pauly's reagent and *N.N.C.D.* reagent. Further, superposition of the tryptophan spot given by the tissue extracts and that given by tryptophan added to such extracts was obtained and a similarity of the colour reactions was observed.

The brain of dog, cat, mouse, guinea pig, rat, rabbit, pigeon, hen and gull contained between 1 and 3 μgm. tryptophan per gm. of fresh tissue, and these concentrations were between 3 and 10 times the corresponding concentrations of 5-hydroxytryptamine. Other tissues in the body such as the spleen, gut and blood also contained 3–10 times as much tryptophan as 5-hydroxytryptamine.

When the various parts of the brain of the dog, cat and rabbit were dissected out and assayed for their tryptophan content, the richest sources were found to be the pons and hypothalamus. The mid-brain medulla and cerebellum contained appreciable quantities whereas the cerebral hemispheres and spinal

Table 1. ESTIMATES OF TRYPTOPHAN AND 5-HYDROXYTRYPTAMINE (µGM /GM. TISSUE) IN DOG BRAIN

Part of brain	Tryptophan	5-Hydroxytryptamine
Cerebral hemispheres	0 1	0·01
Hypothalamus	5–40	0 40
Mid-brain	2–8	0 35
Cerebellum	1–4	0 02
Pons	1–20	0 05
Medulla	2–5	0·25
Spinal cord	0·2	0·02

cord showed only traces. The results for the dog are shown in Table 1 together with estimates of 5-hydroxytryptamine for the corresponding areas. Inspection of the figures shows that the tryptophan content of three areas—the hypothalamus, cerebellum and pons—was about 100 times that of 5-hydroxytryptamine whereas the ratio was only 3–10 for the other parts. A similar result has also been found for cat and rabbit brain. The reason why the hypothalamus, cerebellum and pons are relatively rich in tryptophan and poor in 5-hydroxytryptamine is not clear at present.

Resting Potentials in Isolated Frog Sartorius Fibres at Low External Potassium Concentrations

IN earlier experiments referred to by Conway[1,2], it was shown that the resting potential (E) of isolated frog sartorii fibres corresponded to the theoretical values as determined by the relation:

$$E = \frac{RT}{F} \ln [\mathrm{K}]_o/[\mathrm{K}]_i = \frac{RT}{F} \ln [\mathrm{Cl}]_i/[\mathrm{Cl}]_o \qquad (1)$$

provided the conditions were such that a 'balanced state' (state of zero net flux) existed for the sodium and potassium ions.

The validity of the Conway theory, from which such an equation may be derived, has been well tried and supported by Kusel and Netter[3], by Mond[4], Adrian[5], Hodgkin[6]; Hodgkin and Horowitz[7]; also for mammalian skeletal muscle by Pillat, Kraupp, Giebisch and Stormann[8].

Here various potential measurements using the micro-electrode technique[9] were carried out[10] with fibres of frog sartorii which had been immersed overnight at 0–3° C. in Ringer–Conway fluid with constant sodium concentration, and potassium values up to very high concentrations, as great as 200 mM [11].

A series of determinations was also carried out with the impermeant anion, acetate, replacing all the chloride in the external solution, potassium being substituted for sodium up to high levels, the solution being thus maintained isotonic.

In both these types of experiment the theoretical potential with respect to the potassium ion was obtained above external values greater than 10 mM. Below this level the potential tended to fall below the theoretical figure, corresponding with the observations of Adrian, and of Hodgkin and Horowitz.

Immediate determinations of the resting potential of isolated fibres using Ringer–Conway fluid with normal plasma potassium level of 2·5 mM gave a value of 92·5 ± 0·47 mV., the theoretical figure being 100·1 mV. (the 'fibre water' potassium was 133 mM for the group of frogs used here). Adrian obtained similar results, the average fibre water potassium of his frogs being 139 mM.

The points on the curve of log [K] against E were shown by Hodgkin and Horowitz to be reasonably well fitted at the low potassium levels of 1–10 mM and 20° C. by the relation:

$$E = 58 \log \frac{[\mathrm{K}]_o + 0{\cdot}01\,[\mathrm{Na}]_o}{[\mathrm{K}]_i + 0{\cdot}01\,[\mathrm{Na}]_i} \qquad (2)$$

Above an external concentration of potassium of 10 mM, this equation gives results practically identical with equation 1. The fall below the potential-levels from equation 1 at external values of potassium less than 10 mM could be assigned initially to either of two causes. First, to the existence of a sodium–potassium linked pump which would result in an equation of the second type given above.

It could also arise if a 'balanced state' with respect to sodium and potassium ions did not in fact exist for isolated sartorii fibres with the external potassium concentration less than 10 mM. These two views are also referred to by Hodgkin and Horowitz[7], with the conclusion that their published observations are consistent with either of them.

To examine the question here the observation of Carey and Conway[12] was utilized that with plasma as the external medium the permeability of the fibres to sodium ions was retained closer to the normal.

Plasma was prepared by bleeding through an aortic cannula into a heparinized tube. The blood was centrifuged at once and the plasma analysed for its potassium content, suitably diluting or adding potassium chloride if necessary to give 2 5 mM.

Table 1

External fluid	External potassium concentration	Resting potential observed mV.	Resting potential theoretical mV.
Ringer–Conway	2·5	92 5 ± 0·47	100·1
Plasma	2 5	99·2 ± 0·7	100 1

Such results show that the hypothesis of a sodium–potassium linked pump is unnecessary with respect to the potential measurements for frog skeletal muscle, and is not the explanation of the fall from the theoretical potential values from equation 1, for isolated muscle at low external potassium-levels.

My thanks are due to Prof. E. J. Conway for advice and discussion.

Neutralization of Human Serum and Pituitary Thyrotropic Fractions with Antisera to Bovine Pituitary Thyrotropin

ANTISERA to pituitary growth hormone have been shown to possess a high degree of species specificity[1]. This was demonstrated by precipitin and by neutralization experiments, in which the antiserum to human growth hormone was active against human and monkey growth hormone, but not against growth hormone derived from other species.

Experience over the past years with antisera to a thyrotropic preparation of beef pituitary has revealed that the antisera do not possess great specificity when tested against thyrotropin from several other species[2]. In the present work, the observations have been extended to man. Antibovine thyrotropin sera have been found to neutralize the thyrotropic activity of fractions prepared from human pituitaries and from two individual sera, one from a patient with classical Graves's disease and the other from a healthy euthyroid subject.

Rabbits were immunized by the method of Freund[3], using a commercial bovine thyrotropin preparation in current clinical use ('Thytropar') as the antigen. Details of the methods employed and the results from precipitin and neutralization studies with the parent and other more purified thyrotropic extracts are being published elsewhere. The antibody-containing globulin fraction was concentrated from the antisera and from normal rabbit globulin by sodium sulphate precipitation[4].

The serum fractions were prepared by the method of Bates *et al.*[5]. The human pituitary preparation, not at the final stage of purification, was made by Heideman and Bakke[6] from pooled glands obtained at autopsy and was obtained through their courtesy. The active material contained 10 mμ/c.c.

The hormone to be neutralized and normal serum or antiserum, or the globulin preparation made from antiserum or normal serum, were mixed and kept overnight at 4° C. In one experiment (Exp. 234), previous absorption of both normal and antiserum with bovine serum was conducted prior to mixing. Assay for thyrotropic activity was performed by a slight modification of the method of McKenzie[7]. The iodine-131 content of the blood was measured before and 2 hr. after intravenous injection of the test sample. In each assay, saline, the human pituitary or serum preparation mixed as above with serum or globulin preparation of serum, and two dose-levels of a standard preparation of beef thyrotropin were assayed concurrently. Four mice were employed for each group.

It is evident from Table 1 that there was complete neutralization of human thyrotropin from both pituitary (Exps. 138, 230 and 234) and serum (Exps. 208 and 188) sources by the several anti-bovine thyrotropin sera used. No neutralization occurred when normal rabbit serum was employed. In Exp. 230, the

† Experiment confirmed with an antiserum to a preparation containing 25 μ/mgm. kindly provided by Dr. John G. Pierce, University of California.

‡ Insufficient preparation for test with normal rabbit serum globulin.

normal serum was obtained from the same rabbit in which the antiserum was induced. In Exp. 234, the normal serum was absorbed with normal bovine serum in the same manner as the antiserum. The failure of the bovine serum absorbed antiserum to neutralize the thyrotropin excludes the possibility of precipitation of hormonal activity along with non-specific proteins. The failure of the pre-immune and normal rabbit sera to neutralize excludes the presence of neutralizing substances in serum prior to immunization.

The nature of the material in human serum which induces a thyrotropic response, especially in Graves's disease, has not been as yet clearly identified as thyrotropin. Adams and Purves have observed that the release of iodine-131 from the thyroid is delayed following injection of thyrotoxic serum compared to standard preparations or to hypothyroid serum[8]. They suggested that possibly the thyrotropin in the serum of Graves's disease patients may be abnormal. This observation in the guinea pig has been confirmed in the mouse[7].

More recent work by McKenzie indicates that the material in hyperthyroid sera will cause histological activation of the mouse thyroid, an increased uptake of iodine-131, and an increase in level of protein-bound iodine[9]. This suggests that the active material in the serum is a thyrotropin. The delay before activation of the thyroid, however, by such a sera could also imply that the serum factor is not a thyrotropin, but only acts indirectly to cause the mouse to release its own thyrotropin.

As stated, the present experiments reveal that the thyrotropic effect of the thyroid-activating substances in normal and in hyperthyroid serum were equally well neutralized by an antithyrotropic serum. This suggests that the active material in both is a thyrotropin which is closely similar if not identical to that from the pituitary. It is not proved that endogenous mouse thyrotropin was not secreted and then neutralized by the injected antiserum. However, the extent of the dilution of the antiserum in the circulation of the mouse makes this possibility less likely, as does the short time, 2 hr., between injection and evidence of thyroid response. This allows only a very brief interval for the diluted antibody to have reacted with endogenous thyrotropin were it secreted.

A Substance in Lingcod Liver Oil which prevents Hypercholesterolæmia in Cholesterol-fed Chickens

THE serum cholesterol-level in some animals is elevated above the normal value by the addition of cholesterol to the diet. In certain species, such as the chicken, cholesterol by itself brings about this increase ; but in other species, exemplified by the rat, the presence of cholic acid is also required. The degree of hypercholesterolæmia is altered when certain vegetable and fish oils are added to the diet ; but the observed effect of any one oil is dependent on the species of animal under investigation. De Groot and Reed[1] showed that cod liver oil and corn oil prevented the increase in plasma cholesterol in rats due to dietary cholesterol and cholic acid. Dam *et al.*[2] investigated the effect of dietary cod liver oil and linseed oil in cholesterol-fed chickens, and found that both oils increased the hypercholesterolæmia caused by the dietary cholesterol. Similar experiments on chickens were performed by Wood and Biely[3] using corn oil, tallow and various fish oils. Corn oil, tallow and herring oil were observed to increase the hypercholesterolæmia ; but lingcod liver oil and halibut liver oil completely prevented the appearance of hypercholesterolæmia. Ratfish liver oil, dogfish liver oil and basking shark liver oil were intermediate in effect. In view of the diverse effects of the oils observed in the chicken studies, further investigations were carried out to obtain additional information about the mode of action of the oils. Corn oil, herring oil and lingcod liver oil were chosen for the investigation.

The oils were saponified with ethanolic potassium hydroxide, and the soap solutions were extracted several times with ethyl ether to obtain the unsaponifiable material. The soap solutions were then acidified with hydrochloric acid and the free fatty acids extracted with ethyl ether. The extracts containing the unsaponifiable fractions and the free fatty acids were washed and the solvent removed on a water-bath at 70° C. and under a stream of nitrogen. The oils and their components were added to a diet containing 1 per cent cholesterol. This diet was fed to 2-weeks old New Hampshire chickens for 9 days, after which time blood samples were taken and the serum cholesterol concentrations determined. The oils were fed at a 10 per cent level in the diet and the unsaponifiable substances and the free fatty acids were added in amounts approximating to that obtained from an equivalent amount of oil.

As observed previously, lingcod liver oil prevented the hypercholesterolæmia caused by the dietary cholesterol, and herring oil and corn oil stimulated the rise in serum cholesterol concentration (Table 1). The free fatty acids from all three oils markedly increased the degree of hypercholesterolæmia, whereas

Table 1. EFFECT OF VARIOUS OILS AND FRACTIONS FROM THESE OILS ON SERUM CHOLESTEROL-LEVELS IN CHOLESTEROL-FED CHICKENS

Addition to the cholesterol-containing diet	Serum cholesterol (mgm./100 ml.)
None	192 ± 12*
Corn oil	784 ± 173
Herring oil	648 ± 133
Lingcod liver oil	130 ± 31
Corn oil fatty acids	793 ± 144
Herring oil fatty acids	618 ± 215
Lingcod liver oil fatty acids	702 ± 158
Corn oil unsaponifiables	193 ± 21
Herring oil unsaponifiables	237 ± 34
Lingcod liver oil unsaponifiables	119 ± 17

* Each value is the mean for four samples of serum ± the standard deviation. Each sample contained the serum from four chickens.

the unsaponifiable material from herring oil and corn oil produced only a slight increase or none at all. The unsaponifiable portion of lingcod liver oil, however, completely prevented the rise in serum cholesterol-level.

It was concluded that the ability of lingcod liver oil to prevent hypercholesterolæmia in cholesterol-fed chickens depends on the presence of some compound or compounds in the unsaponifiable material of the oil. At the present moment the active material has not been identified; but the possibility exists that it may be vitamin A or perhaps a sterol-type compound which acts in a similar manner to cholestanol. The latter compound was shown[4] to prevent effectively the appearance of hypercholesterolæmia induced in chickens by cholesterol feeding.

SEROLOGY

A Starch Gel Immunoelectrophoretic Analysis of Human γ-Globulin demonstrating the Inter- and Intra-Specific Variation of Organisms

AN age-dependent, phenotypic variation in the antigenic composition of human γ_2-globulin has been reported[1-3]. Chicken antisera to preparations rich in γ-globulin (for example, *FrII*) were used to examine human sera by the starch gel immunoelectrophoretic method of Poulik[4] as modified by Goodman[3,5]. Certain of these antisera detected in many instances more than one component in that portion of the γ-globulin which moves backward from the origin in starch gel electrophoresis, that is, in the γ_2 fraction of serum. Recently, as the point of departure for the present work, non-human primate sera were also examined by some of the antisera. It was reasoned that, since the evolutionary continuum leads from the intra- to the inter-specific variation of organisms, the serum antigenic specificities which differ between human beings would fail to have derivative counterparts in the sera of the non-human primates. A considerable body of data illustrating the applications of this reasoning has now been gathered, and several examples of the data are presented in Figs. 1 and 2.

The immunoelectrophoretic reactions depicted in Fig. 1 show that the absorption of chicken antiserum with rhesus monkey serum selectively lowers the antibody concentration to the predominant antigenic groupings of human γ-globulin and thus permits a visualization of those groupings held by only a fraction of the γ_2-globulin molecules, a fraction which varies markedly between human beings, and which appears to occur more richly in adult sera than in prepuberty sera[2,3]. Note that such a fraction could be detected in the 'positive' human serum pool (made up of several adult sera) after antisera *C*-341 and *C*-342 were absorbed with the rhesus serum. The fragmented γ_2-globulin precipitin arc signifying a positive reaction was observed with single serum specimens as well as with the 'positive' pool. (An example of such a result is photographically reproduced in Fig. 1*E*.) On the other hand, a large number of the serum specimens from adults and children, as well as the 'negative' pool (made up of several prepuberty sera), failed to yield the second γ_2 reaction with these two reagents.

The results obtained with the antisera, *C*-79 and *C*-82, present a somewhat different picture, for these antisera each contained, as compared to *C*-341 and *C*-432, antibody directed to a large percentage of the spectrum of antigenic groupings showing an inter-specific variation between man and monkey. The additional γ_2 arc developed with the 'negative' pool as well as with the 'positive' pool. However, Fig. 1 (*C* II and *D* II) does show that the absorption with the rhesus serum left a more potent reaction for the variant γ_2 fraction of the 'positive' pool than for that of the 'negative' pool.

A number of human and non-human primate sera have now been surveyed for the presence or absence of the additional γ_2 reaction by unabsorbed *C*-79 and by *C*-82 after an absorption with a small quantity

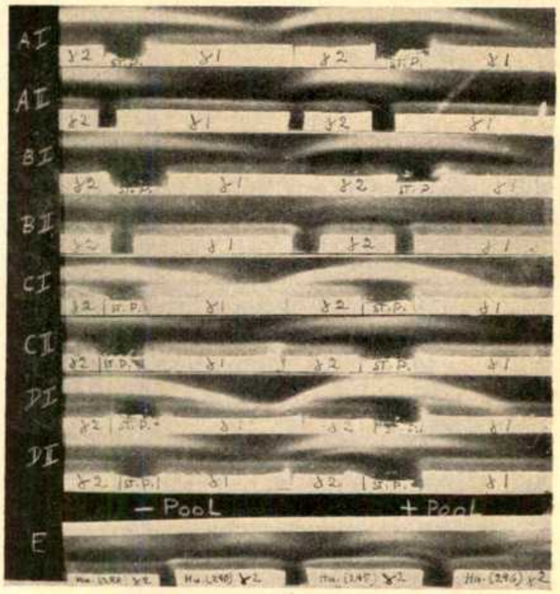

Fig. 1. Photographs of the reactions by double diffusion in agar gel of chicken anti-human γ-globulin sera against human serum separated by starch-gel electrophoresis. From *A* to *D* each reaction tray contains at its bottom the γ-globulin portions from the starch-gel separation of a 'negative' human serum pool and a 'positive' human serum pool (see text). Four different antisera are represented: *C*-341 in *B*, *C*-82 in *C* and *C*-79 in *D*. In each instance the reactions of the antiserum before absorption (I) are compared to those obtained after an absorption (II) with an aliquot of rhesus monkey serum estimated to contain 198 mcgm. γ-globulin per ml. of antiserum. In *E* the rhesus absorbed *C*-341 reacts against the γ_2-globulin portions of four different adult human sera. The second γ_2-precipitin arc is marked in samples 295 and 296 but weak to negative in samples 288 and 290. The non-specific lateral band that develops in the agar near the surface of the starch gel block can be so recognized and thus discounted in assessing the specific antibody–antigen reactions. γ_2, The γ_2-globulin portion of the starch gel block; *st.p.*, starch paste, in which the serum sample was originally inserted: γ_1, the γ_1-globulin of the starch gel block

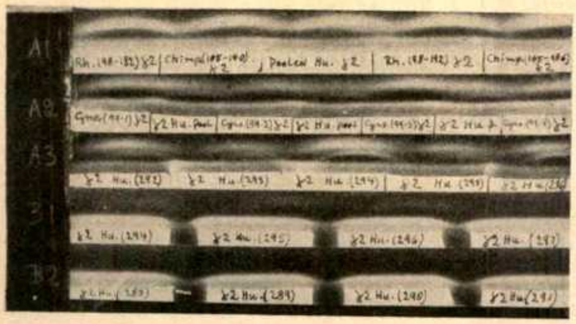

Fig. 2. Photographs of immunoelectrophoretic results obtained on surveying sera from the rhesus monkey (*Rh*), the cynomolgus monkey (*Cyno*), the chimpanzee (*Chimp*), and the human (*Hu*) for the presence or absence of a 'minor' γ_2-globulin antigen as detected by absorbed antiserum *C*-82 reacting against the γ_2-globulin portion (γ_2) of the starch gel blocks. For the *A* trays, *C*-82 was absorbed per ml. with an aliquot of 'negative' human serum estimated to contain 125 mcgm. of γ-globulin. A 'minor' γ_2-reaction occurring underneath the 'major' precipitin reaction can be seen only for the human samples. In the *B* trays, *C*-82 was absorbed per ml. with 410 mcgm. of γ-globulin of the appropriate human serum. In the two trays represented positive reactions can only be seen for human sera 294, 295 and 296. It is of interest that 294, 295, 296 and 297 are *Gm*-like (−) samples and 288, 289, 290 and 291 are *Gm*-like (+) samples. (The absorbed *C*-82, however, was not the best reagent of those tried for distinguishing *Gm*-like (−) samples from *Gm*-like (+) samples.)

of the 'negative' human serum pool which by weakening the predominant precipitin arc allowed the additional γ_2 arc to be fully revealed. All the adult human sera tested (14 samples with *C*-79 and 39 with *C*-82) yielded this additional reaction, though to varying degrees, but none of the non-human primate sera did. The survey has encompassed sera from 13 chimpanzees, a gibbon, 16 rhesus monkeys, 15 cynomolgus monkeys, 2 baboons, 2 mandrills, a langur, 2 spider monkeys, and a capuchin monkey. Examples of the results obtained in the survey are presented in Fig. 2*A*. Also note (Fig. 2*B*) that when *C*-82 was so absorbed with the appropriate serum pool that it could no longer yield in immunoelectrophoresis its 'major' γ-globulin precipitin arc, its 'minor' γ_2-precipitin arc (the one missing from non-human primates) was no longer developed by all human adult sera, but only by some.

The relationship of the antigenic components detected by such chicken antiserum reagents to the *Gm* groups[6] is now under investigation. For this purpose Dr. Grubb has kindly furnished 6 *Gm* (*a* +) sera and 6 *Gm* (*a* −) sera. Similarly, Dr. Steinberg has kindly furnished 6 of his *Gm*-like (+) sera which are present in some Negroes and rare or absent in whites, and 6 of his *Gm*-like (−) sera[7]. Although none of the reagents has distinguished the *Gm* (*a* +) group from the *Gm* (a −) group (each yielding positive and negative reactions with both groups), some of these reagents did distinguish the *Gm*-like (+) group from the *Gm*-like (−) group in that they reacted only with *Gm*-like (−) samples and not with the *Gm*-like (+) samples. The interrelationships of such γ-globulin specificities may prove to be so complex as to argue for the thought that genetic information inherited through a number of gene loci rather than just through a *Gm* locus[8] goes into shaping the antigenic architecture of a γ_2-globulin molecule. In this regard, an answer is being sought to the crucial question of whether there is in addition to the variant antigenic configurations detected an overall antigenic resemblance between the above 'major' and 'minor' fractions of the γ_2-globulin of human serum.

This investigation was aided in part by research grants from the National Institutes of Mental Health and the (American) National Multiple Sclerosis Society. I am indebted to Dr. Albert B. Sabin at the Children's Hospital Research Foundation in Cincinnati, and to Dr. Sidney Gains, chief of the Department of Microbiology at the Walter Reed Army Institute of Research, for providing me with the chimpanzee serum, and to Dr. G. D. Brigham, director of the Biological Division at Parke, Davis and Co., for the rhesus and cynomolgus monkey sera. I am also grateful to Dr. George B. Rabb, curator of the Chicago Zoological Park, for the many samples of primate sera. The expert assistance of Emily Poulik, Roger Gudobba, and Rosemarie McBride is greatly appreciated.

Changes in Outdated Human γ-Globulin Preparations

THE fate of antibodies in normal human γ-globulin preparations during storage was studied by Gerlough[1], who succeeded in achieving surprising results: the half-time of diphtheria antitoxin in the preparation was 23 years—under strict storage conditions even 40–69 years. Tiselius electrophoresis and ultracentrifugation did not reveal cleavage or denaturation of the protein molecule.

We have studied a number of outdated normal human (plasmatic) γ-globulin preparations prepared by Cohn's classical methods 6 and 9 as well as by other methods. The products were stored at + 4° C. for 3–6 years in the form of sterile solutions. No difference was observed in the contents of diphtheria antitoxin compared with fresh products, though immunoelectrophoretically two atypical fractions besides the normal precipitation line were noticed. Of these atypical fractions one possessed a mobility lower (called γ_X) and the other higher (γ_Y) than γ-globulin. The γ_Y component appears sooner than the γ_X one, so that some of the preparations studied possessed only the γ_Y component and some both of them. Both fractions are not precipitated by antisera with saturated anti-γ-globulin antibodies. Fig. 1 presents two γ-globulin products prepared four years ago by Cohn's classical method. These products were originally absolutely homogeneous. When studying the γ-globulins prepared from materials containing hæm and hæmoglobin a similar phenomenon was observed, and even much sooner after the preparation of solution: the time after which the fractions begin to appear is in case of plasmatic preparations a matter of years—in case of placental preparations of the order of months.

Plasmatic and placental products stored one year at + 4° C. were compared by quantitative precipita-

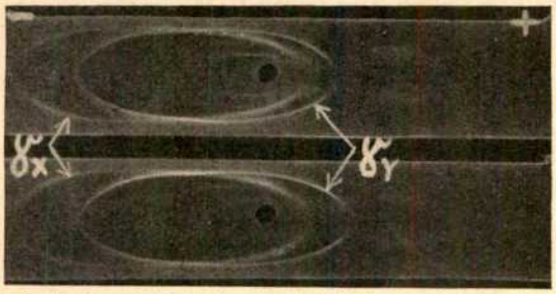

Fig. 1. Immunoelectrophoresis of γ-globulin prepared according to Cohn, aged for 3 yr. at + 4° C.

tion with antihuman antiserum by the capillary tube technique with the following results: plasmatic γ-globulins not yet split were precipitated in a considerably higher dilution (1 : 2,000–4,000) than placental preparations—already split (1 : 32–128). This fact indicates a partial destruction of groups determining the species specificity of the protein in the course of splitting.

The changes in γ-globulins during storage result from a slow proteolytic process. Fractions having identical electrophoretic mobility were obtained by trypsin-, plasmin-, and papain-digestion of a standard γ-globulin. No such manifestations were observed when pepsin-digestion was applied.

The γ-globulin fractions resulting either from storage or from tryptic-digestion can be partially separated by ammonium sulphate precipitation. In Fig. 2 are (from above downwards) immunoelectropherograms of the original outdated product prepared from hæmolysed materials, and fractions appearing after 25 per cent, 25–30 per cent, 30–35 per cent, and 35–50 per cent saturation. At more than 50 per cent only the γ_X component is precipitated. The fraction between 35 and 50 per cent contains a mixture of γ_X and γ_Y component without the original γ-globulin. It is interesting that these two proteins behave as immunologically different antigens, judging from the site of arc-contact according to Ouchterlony's principle[2].

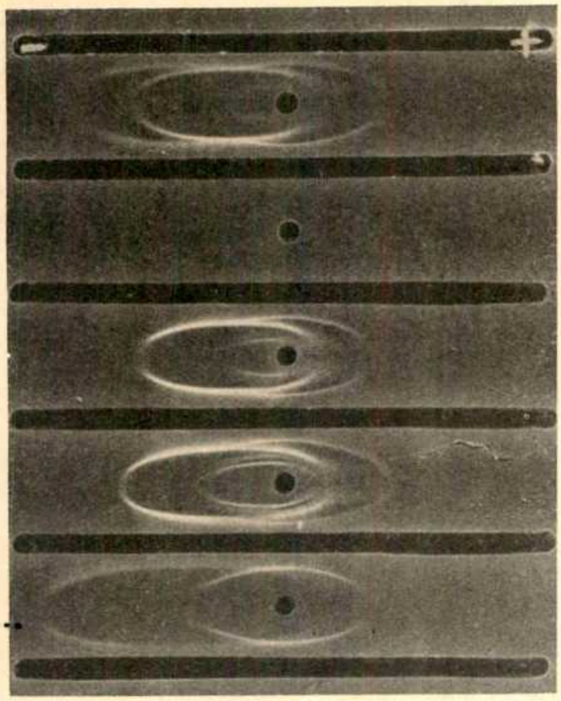

Fig. 2. Ammonium sulphate fractionation of spontaneously split γ-globulin from hæmolysed material

Among the products studied was also a sample of γ-globulin prepared experimentally by Lever's modification of Cohn's method 10 from placentæ[3]. This preparation contained in the final 16 per cent solution approximately 0·3 per cent of sodium tartarate as a remainder from the production technique. In this product both the above-mentioned fractions appeared in the course of a few months accompanied simultaneously by the formation of a considerably large quantity of small needle-like crystals showing a pearly glossy colouring after shaking (Fig. 3). Immunoelectrophoresis of isolated, washed and recrystallized particles revealed that their protein component was formed by the atypical γ_Y fraction. The structure of the crystals and the role of the other ingredients present in the solution will be studied in detail in the future. By ultracentrifugation of the original, spontaneously storage-split product two fractions were isolated, one having S_{20} 4·8, the other 8·2; the solution of the crystalline fraction was homogeneous in the ultracentrifugation, having S_{20} 4·4.

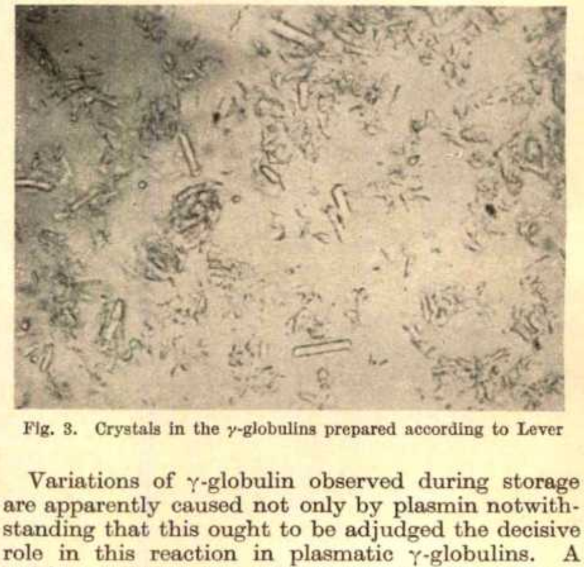

Fig. 3. Crystals in the γ-globulins prepared according to Lever

Variations of γ-globulin observed during storage are apparently caused not only by plasmin notwithstanding that this ought to be adjudged the decisive role in this reaction in plasmatic γ-globulins. A quicker splitting in products prepared from hæmolysed materials indicates the share of 'neutral' enzymes present in erythrocytes[4]. The appearance of crystalline atypical fraction seems to indicate the analogy with γ-globulin fraction III isolated by Porter[5] by papain-digestion of rabbit γ-globulin, but regardless of the crystalline structure.

Further details of our observations will be published elsewhere.

Effect of Amethopterin and 6-Mercaptopurine on the Pattern of Oxygen Tension Measurements in the Fluid Phase of Serum Agar Cultures of Bone Marrow Flecks

We have recently described an electro-chemical method of measuring the oxygen tension in the fluid phase of serum agar cultures of bone marrow flecks[1]. Oxygen tension decreased, at first fairly quickly and then more slowly over a period of three days. This was ascribed to the utilization of oxygen by the surviving cells. In this communication we describe some preliminary experiments upon the effect of amethopterin and 6-mercaptopurine on the oxygen tension pattern of similar cultures. At the beginning of the experiments the culture fluid was equilibrated with air containing 5 per cent carbon dioxide; the carbon dioxide was required to keep the *p*H of the fluid in the physiological range. After a number of hours the fluid was replaced either with fresh medium alone or with medium containing the drugs. As this fluid was also equilibrated with the air–carbon dioxide mixture, the oxygen tension rose but not usually to the starting level. This may have been due to the mixing of the fresh medium with the relatively anoxic serum agar also present in the culture chamber. Thereafter, in the normal controls the oxygen tension continued to fall until the experiment was concluded. This is illustrated by the control curve seen in Fig. 1.

When a medium containing a 1 m*M* concentration of amethopterin was added to the culture of normal marrow there was a definite alteration in the pattern which is illustrated in Fig. 1. After a latent period of about 8 hr. the curve flattened; this we think is due to interference with the normal oxygen metabolism of the cells. It did not occur in 0·25 m*M* concentrations; 0·5 m*M* concentrations showed an intermediate effect.

The findings with 6-mercaptopurine were comparable. We found that a 6-m*M* concentration caused a flattening in the oxygen tension curve after a latent period of about 20 hr.; this did not occur with 2-m*M* concentrations and 4-m*M* concentrations had an intermediate effect.

The oxygen tension patterns of the fluid phase of serum agar cultures of marrow flecks from a case of acute leukæmia have also been studied. The patient, a woman aged forty, was admitted to hospital with pneumonia. The peripheral blood showed a subleukæmic picture, and the bone marrow was stuffed with primitive leukæmic cells. After a stormy course and treatment with antibiotics, steroids and 6-mercaptopurine a remission was induced. This lasted 5 months, after which relapse and death occurred. At no time was the patient given antifolic drugs. At the time of the cell culture the marrow showed predominantly primitive leukæmic cells. Four cultures were made without the addition of drugs, and the oxygen tension patterns resembled those found in normal marrow. 6-mercaptopurine was added to three cultures in concentrations of 6, 4 and 2 m*M*, respectively. The curve obtained with the culture containing the 6-m*M* concentration showed a levelling after about 10 hr.; those obtained from the 4- and 2-m*M* concentrations continued downwards. Amethopterin was added to three cultures in concentrations of 1, 0·5 and 0·25 m*M* respectively; in none of these was a levelling effect seen.

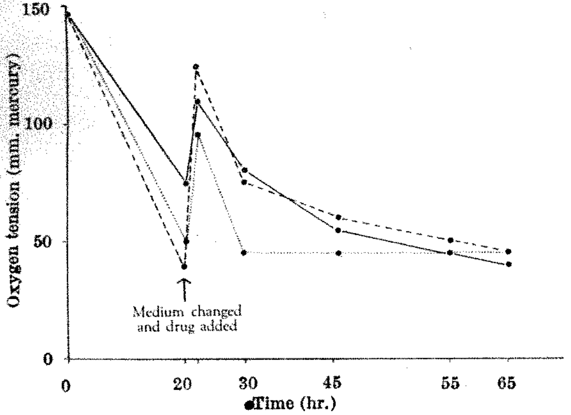

Fig. 1 ●—●, No drug control; ●···●, 1 m*M* amethopterin; ●- - -●, 0·25 m*M* amethopterin

These preliminary results are of interest because they could form the basis of an *in vitro* test of the sensitivity of leukæmic marrow cells to various chemotherapeutic agents. This would be based on the hypothesis that the concentrations of drugs which would inhibit the oxygen uptake of sensitive cells might not affect cells which were resistant.

We are grateful to Messrs. Lederle and Burroughs Wellcome for a supply of drugs.

PLANT PHYSIOLOGY

Effect of Gibberellic Acid on Flower Differentiation in Petkus Winter Rye

It is known that application of gibberellic acid causes flowering of many biennials (*Hyoscyamus*, *Apium*, *Brassica*, *Daucus*, etc.)[1]. In these cases gibberellic acid substitutes for cold (vernalization) treatment. Treatment of winter cereals (Petkus rye[2], barley[3], winter wheat[4]) with gibberellic acid, on the contrary, has been found to have no effect on the induction of normal flowers. Chaylakhian[5] has reported that treatment of non-vernalized oats, variety Victory, with gibberellic acid, under short-day conditions, caused formation of an increased number of developed panicles. This was not the case under long-day conditions. Paleg and Aspinall[3] have reported that treatment of barley with gibberellic acid for several weeks immediately following emergence results in the formation of abnormal spikes.

The experiments reported here are concerned with the normal flower formation of Petkus winter rye by application of gibberellic acid. This cereal is, under the growing conditions of our experiments, a cold-requiring plant.

It has been found that, to be successful, treatment must occur at a particular stage in the development of the plant.

All the experiments were performed under the controlled greenhouse conditions of the Earhart Plant Research Laboratory. A description of this laboratory and the experimental facilities available in it has been given by Went[6].

Plants of winter Petkus rye, grown under a constant temperature of 17° C., both in short-day (8 hr.) and long-day (16 hr.) regimes, were sprayed with water solutions of gibberellic acid (200 p.p.m.). The plants of each day-length regimen were divided into three groups: (1) controls, sprayed with de-ionized water; (2) spray treatment started when the plants had five visible leaves; (3) spray treatment started when the plants had ten visible leaves. Each group was composed of 18 plants. The plants were sprayed for seven successive days after which they were permitted to develop without further treatment.

75 days after sowing the seed the plants were dissected and the stage of development of the growing point of each main shoot recorded. For the five-leaf stage this dissection occurred 48 days after the end of treatment; for the ten-leaf stage, 12 days after treatment. In order to evaluate the stage of development, an arbitrary numerical scale from 0 to 4 was used, in which stage 0 is the early vegetative apex and 4 is a complete flower just prior to full development of the awns.

The results (Table 1) show that winter Petkus rye which has not been vernalized can be induced to form normal flowers by the application of gibberellic acid. The application of the hormone apparently must, however, occur at a proper time in the development of the plant (ten-leaf stage). Applied before this time, gibberellic acid does not induce flowering. It is, on the contrary, inhibitory. The typical effect of gibberellic acid on growth in grasses is found in both the early and the later applications of the acid, that is, elongation of the internodes and narrowing of the leaves.

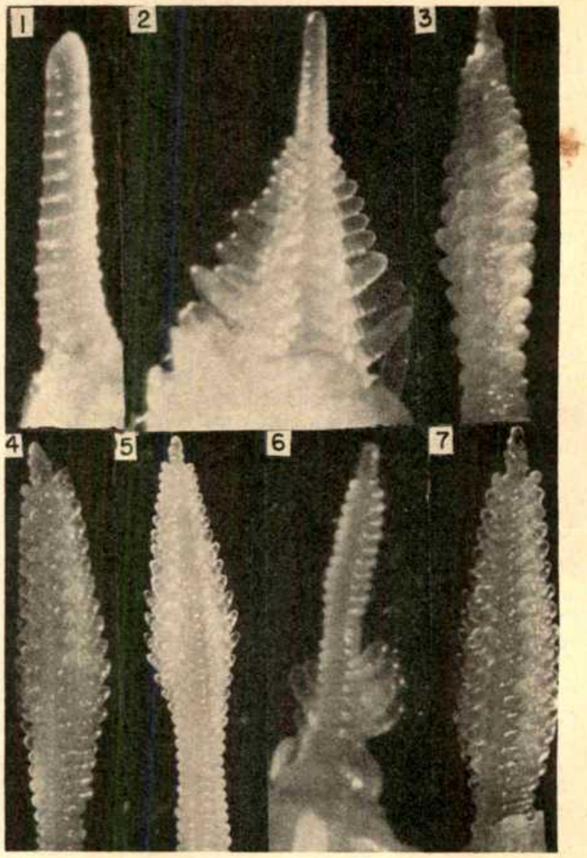
Table 1. EFFECT OF GIBBERELLIC ACID ON THE FLOWERING BEHAVIOUR OF WINTER PETKUS RYE

Treatment with 200 p.p.m. at the	Long day	Short day
Five-leaf stage	Veg./abnormal* 18 plants	Veg./abnormal 13 plants* Flower/abnormal 4 plants 17 plants
Ten-leaf stage	Flower primordia (stages 3–4)* 18 plants	Flower primordia (stage 4 to head)* 18 plants
Control (water spray)	Vegetative* 17 plants	Flower primordia (stages 3–4) 10 plants Veg. primordia 8 plants 18 plants

* See Figs. 1–7 for a description of these developmental stages.

Figs. 1, 2 and 3 are photographs of typical apices of the three treatments on long day. Fig. 1 shows the apex of a control plant after 75 days of growth. The plants are all vegetative. Fig. 2 shows the effect on the growing point of applications of gibberellic acid at the five-leaf stage. It can be seen that the lower part of the apex is abnormal with great numbers of developing tillers. The upper part is normally vegetative. We consider this portion of the apex as having been developed after the effect of the applied gibberellic acid has ceased. Fig. 3 shows a typical apex from a plant treated after the tenth leaf has unfolded. This is a normal flowering apex as can be seen by comparison with Fig. 4, which represents an apex dissected from a vernalized control plant at the same stage of development as that shown in Fig. 3.

Figs. 5, 6 and 7 represent apices dissected from plants grown on short days. Fig. 5 pictures the unvernalized apex of a control plant; because of the promotive effect of short days on flower formation in unvernalized winter rye (short-day vernalization: see ref. 7), this apex is further advanced than comparable apices of plants grown on a long-day regimen and shows an early stage of flower development. Fig. 6 shows the effect of gibberellic acid treatment at the fifth-leaf stage. These plants show a distinct abnormality at the base of the apex with an early stage of a normal flower at the top of the apex. Fig. 7 shows the effect of gibberellic acid treatment at a later stage (10 leaves).



Figs. 1–7. Stem apices of control, vernalized and gibberellic acid-treated plants

On short day there is a significant difference between controls and those plants treated at the ten-leaf stage in the number of plants which flowered at the time of dissection, as well as the stage of development. Only 5 per cent of the controls had well-developed flower primordia, while all the plants treated at the ten-leaf stage had advanced flower primordia. Treatment at the five-leaf stage on short days resulted not only in abnormalities, but also the upper part of the apex, on which flowering had started, was at a significantly earlier stage in development of the flower.

Considering the long-day experiments, it is obvious that the plants must reach a specific stage of development before they can be induced to flower. Purvis and Gregory[7,8] have shown that there is a minimal leaf number (7) before flowering in winter rye can occur. The primordia above the eighth leaf are indeterminate and can produce either leaf or spikelet. In our experiments the plants in which gibberellic acid caused flowering had 10 exposed leaves, which means that the number of leaves and primordia totalled between 20 and 25. Gibberellic acid applied at this stage affects the development of the labile primordia so that flowers rather than leaves are formed. Since gibberellic acid affects flower formation in plants only after the ten-leaf stage, the acid or a similar substance must be limiting, while 'florigen' is not.

In our experiments and especially in those of Paleg and Aspinall[3], it has been shown that applications of gibberellic acid at an early stage in the development (before the ten-leaf stage) will result in inhibition of flowering. Therefore this early application must either inhibit the formation of, or destroy, the florigen.

Hence, at least two things must happen during vernalization: (1) 'florigen' must be formed, or its formation induced after removal from cold; (2) a gibberellic acid-like substance must also be made, accumulated, or its formation induced so that it is formed soon after the plant is removed from the cold.

A more detailed report of this work is being prepared for publication elsewhere.

Effect of Gibberellin on the Flower Initiation and Stem Extension in Petkus Winter Rye

THE cold requirement for flower formation in biennial *Hyoscyamus niger* was shown by Lang[1] to be replaceable by application of gibberellin, but no flowering response was observed at that time in either Petkus winter or spring rye similarly treated[2]. In 1958, I attempted to supplement partial vernalization in Petkus winter rye by a single injection of gibberellic acid (10 p.p.m.) through the third leaf. No effect on flower initiation was observed. Stem extension was unaffected in the unvernalized controls but considerably enhanced in the partially vernalized series. In 1959, further work was carried out to determine whether the lack of response was due to the low concentration of the single application of gibberellic acid, or whether stimulation of stem extension demanded some prior degree of flower initiation.

Unvernalized winter rye was injected with gibberellic acid at 20 p.p.m.; this was done by feeding through the severed tips of mature leaves. Three groups received single injections to the third, sixth and ninth leaves, respectively, at the time when these had reached full expansion (that is, approximately at intervals of 3 weeks). In a fourth group the sixth and ninth leaves were injected as they reached maturity, while in a fifth group the third, sixth and ninth leaves were treated in turn.

The results are presented in Table 1, in which the effects on progress of flower initiation as 'scores' attained 93 days after planting, and on stem extension, are shown. 'Scores' less than 21 indicate that flower initiation (double ridges) had not been attained, while higher values mark progress beyond this stage.

Stem extension. A single injection at the third-leaf stage had no effect, as was also found in 1958. Single injections at the sixth or ninth leaf-stages resulted in limited stem extension (3 cm. in each case), apparently attained at a higher rate when the ninth leaf was treated. Multiple injections produced an effect rather more than proportional to the number of leaves injected. Thus an injection of the third leaf, apparently ineffective when this leaf alone was treated, intensified the response to treatment of later leaves.

Flowering response. The flowering response was entirely different. Injection of the third leaf resulted in a very small increase in 'score' just below the significant level. Injection of the sixth leaf resulted in a significant increase, which was further augmented by injecting the ninth leaf. Multiple injections effected no greater increase than that following a single injection of the ninth leaf; indeed, the triple injection decreased the score significantly below that due to the single injection.

Although the plants were not grown to maturity, it was evident that those injected through the ninth leaf alone would have produced ears free from morphological abnormalities. Where earlier leaves had been injected in addition, very many abnormalities were found, such as the formation of subsidiary ears from basal primordia ('miracle' ears), leafy outgrowths below the spikelets, or shortening and distortion of the peduncle[3]. This was also true to a lesser degree where the sixth leaf had been injected, but was not, of course, apparent in the undifferentiated apices of plants treated at the third leaf. These effects correspond closely with those obtained by Caso *et al.* (preceding communication).

Thus it appears that gibberellin has no direct effect on flower induction in Petkus winter rye, and therefore cannot replace low temperature in this respect; the accelerating effect on flowering would appear to operate at some post-inductive stage. The stimulus to stem extension only occurs either just before or after flower initiation has taken place.

Table 1. EFFECT OF INJECTING UNVERNALIZED WINTER RYE WITH GIBBERELLIC ACID (20 P.P.M.) THROUGH DIFFERENT LEAVES

No. of injections Leaf injected	0 None	1 3	1 6	1 9	2 6 + 9	3 3 + 6 + 9

BIOLOGY

Rare-Earth Fatty Liver

THE biological behaviour of the rare earths has recently become a question of increasing importance[1]. Early recognition of the prominent occurrence of several of these elements in fission products[2] stimulated a wide scope of distribution studies in animals and, to a limited extent, in man. Yet, we could find among these studies no mention of a specific biochemical or histological effect except for a brief communication from this laboratory on fatty liver degeneration[3] and some earlier reports on rare earths as anticoagulants[4].

We recently characterized the occurrence of an acute fatty infiltration of liver caused by the stable rare earths of lower atomic number (lanthanum to samarium) when they are administered intravenously to rats. The fatty response, which is represented by an increase in the neutral esterified fatty acids with little change in the phospholipid or cholesterol content, is influenced by a variety of hormonal factors[5]. This communication gives results that show the effect of time on recovery of the rat liver from the lipid disorder and the liver lipid response of certain other species when a rare earth is administered.

Female rats (Carworth Farm-Nelson) weighing 180–240 gm. were used in the time study which is summarized in Fig. 1. Pertinent information for the various species used in the other study is included in Table 1 along with the results. All animals in both experiments were fasted 24 hr. before they were killed. The materials and the methods of extraction and measurement of total liver lipids were the same as those used previously[5].

Fig. 1 shows that the maximal increase in liver lipids after a 2 mgm./kgm. dose of stable cerium occurs at 2–3 days. Six days after receiving the cerium injection the liver lipids returned to normal. The recovery period, the fourth to fifth day, shows a wide biological variation. Some preliminary studies indicate that the amount of cerium in the liver remains at essentially the same high level (about 70 per cent of the administered dose) at least from 4 hr. to 12 days (Rafter, J. J., Kyker, G. C., and Snyder, F., unpublished results); that is, there is no tendency for the liver cerium concentration to decrease during the recovery phase.

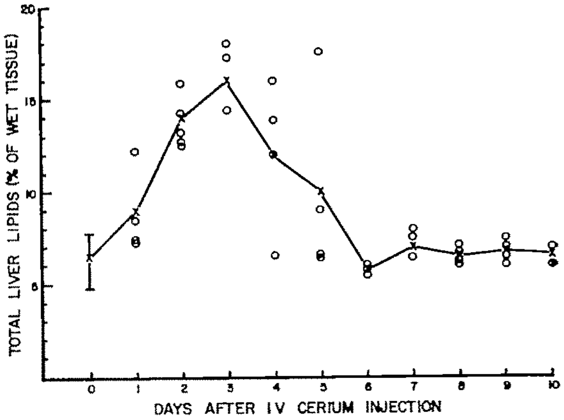

Fig. 1. Total liver lipids as a function of time after intravenous cerium (2 mgm./kgm. in rats). ○, Individual rat value; ○, two individual rat values are identical; ×, mean value. The range is shown for the control group (0 days) with the mean value based on analyses of 18 rats

Because cerium appears to be rather representative for studying the behaviour of the first part of the rare-earth series, this element has been used to survey the lipid response in both males and females of other species under the same conditions that had caused the fat disturbance in rats. The results in Table 1 show a significant elevation in liver lipids for rats (at 3·5 mgm./kgm. for females and 14·0 mgm./kgm. for males), mice (at 7·0 and 14·0 mgm./kgm. for females), and hamsters (at 7·0 and 14·0 mgm./kgm. for males). No fatty livers were seen in any of the other species except in two male rabbits that had 14·7 and 18·2 per cent liver lipids at 48 hr. after a 3·5 mgm. cerium dose. This variation in

Quantitative Estimations of Populations of the River Crab, *Potamon* (*Potamonautes*) *perlatus* (M. Edw.), in Rhodesian Trout Streams

THE river crab is the largest invertebrate to occur in Rhodesian trout streams, but standard quantitative sampling methods reveal insignificant numbers of this animal. As has been suggested by Van Someren in Kenya[1], it is doubtful if anglers have been correct in assuming that the crab is an important trout-food item. Nevertheless, preliminary Rhodesian studies[2] indicate that it occurs in trout stomachs with a median percentage frequency occurrence of 13·1; furthermore, there is a 100·0 per cent frequency and 97·5 per cent volumetric occurrence in droppings of the clawless otter, *Aonyx capensis* Schinz. These figures are based upon slightly more than 1,000 stomach contents, and exactly 1,000 otter samples. In such circumstances the river crab takes on a certain economic standing, even if ignored as a competitor or scavenger.

The known Rhodesian habitat of *P. perlatus* (var. *inflatus*, *depressus*, *sidneyi*) can be described as mountain streams having an altitude ranging from 5,000 to some 6,800 ft. a.m.s.l. (1,520–2,070 m.), although the species may well be found both above and below these limits in addition to occurring in weirs or dams built upon the streams. In these waters the crabs can be taken in funnel-entrance traps baited with fresh fish, and if such traps are enclosed within a screened but typical section of stream then the number of animals captured decreases each time the traps are cleared. Thus it is possible to apply the population estimation method of De Lury[3], in which numbers of animals captured are plotted graphically against an ordinate, and total catch to date against an abscissa. Extrapolation of a fitted straight line to an intersection with the abscissa provides an estimation of the population present at that time. In practice, traps are cleared each 24 hr., and there is little difficulty in relating the results of test areas to the total area of stream-bed under consideration.

Chemical destruction of soft and hard parts of adult crabs suggests that the wet weight of soft parts represents but about 34·0 per cent of total wet weight. In assessing populations as potential fish or otter food this factor should be taken into account. It may be recalled that Allen[4] treated the mollusc *Potamopyrgus* in similar fashion, although that worker dealt with dry weights.

Trapping is selective in that small specimens having a maximum carapace width of less than 17·0 mm. are not attracted to baits so far tested. However, the larger size groups consistently taken in traps can usefully be discarded when taken in orthodox net or dredge samples. In impoverished African trout waters the occurrence of a single large crab can have a grossly distorting effect upon the collection, and when such large-size animals appear it is an asset to be able to ignore their occurrence. The small-size group, in Rhodesian trout streams being less than 17·0 mm. carapace width, have less distorting effect and may be incorporated in orthodox sampling results. During practical field work it is therefore suggested that trapping forms a valuable adjunct to a series of dredge and net samples, provided that the degree of selectivity is determined and allowed for.

Preliminary results at Inyanga, the main trout area of Central Africa and having a central point at about 32° 44′ E., 18° 17′ S., indicate that *perlatus* specimens subject to trapping range from 17·3 to 45·0 mm. maximum carapace width. The range for males is 22·0–45·0 mm., and that for females 17·3–37·5 mm. The median wet weight of all specimens taken, after drying-off of all surplus moisture, ranges from 7·375 to 10·510 gm. There is some evidence that smaller size groups pertain where other trout food organisms are in poor supply; but in these areas the crabs are infested with a small greenish leech, normally some 10·0 mm. in length when extended, and customarily found at the bases of the legs. To date no phoresic associations with the crabs have been detected, such as the phoresis between *Potamon niloticus* and immature stages of *Simulium neavei*, and between a crab species and *S. nyasalandicum*[5]. Calculated populations of river crabs in Rhodesian trout streams range from 3,049 to 5,227 per acre (7,530–12,910 per hectare). The wet weight per acre ranges from 49·5 to 121·2 lb. (55·5–135·8 kgm. per hectare), and the wet flesh weight from approximately 16·82 to 41·2 lb. per acre (about 18·86–46·15 kgm. per hectare).

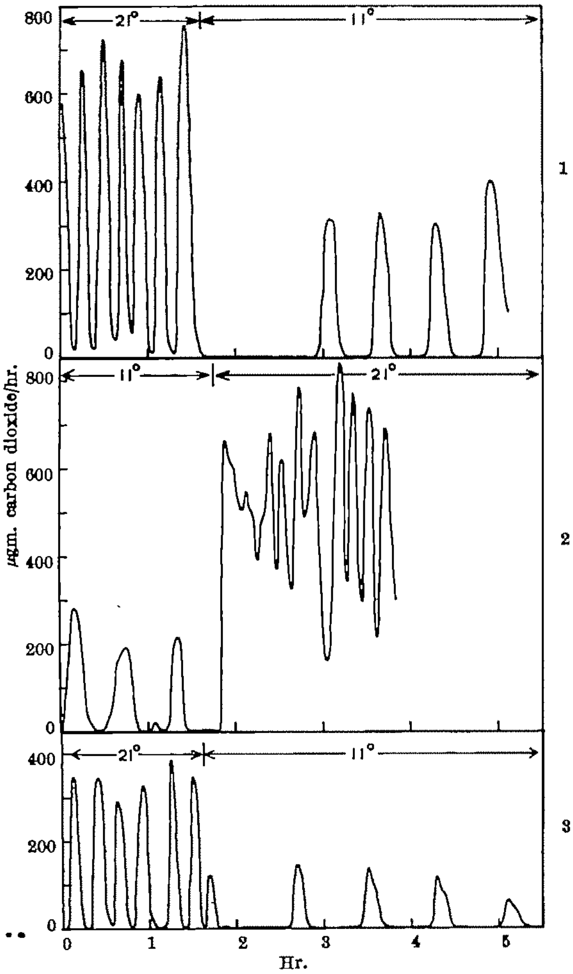
A Temperature-dependent Endogenous Rhythm in the Rate of Carbon Dioxide Output of *Periplaneta americana*

Ball, Dyke and Wilkins[1] and Wilkins[2] developed an apparatus, incorporating an infra-red gas analyser (Grubb-Parsons, *S.B.*1), for continuously estimating the rate of carbon dioxide metabolism of plant tissue maintained under constant external conditions for 5–10 days. Using this apparatus the rate of carbon dioxide output of individual adult cockroaches was determined. The insects were kept in 12 : 12 hr. alternations of light and darkness and, at the commencement of an experiment, were transferred to a small flask which was placed in darkness and at a constant temperature at the end of a light period. The records presented here were derived from one insect, but five other cockroaches gave closely similar results.

In a stream of air initially free from carbon dioxide (relative humidity 80–90 per cent), darkness and at 21 ± 0·1° C. the period of the rhythm was 14·1 ± 0·8 min. (Fig. 1). On lowering the temperature to 11 ± 0·1° C. carbon dioxide output ceased for 76 min. and then the rhythm recommenced with a period of 35·8 ± 1·4 min. and with an amplitude approximately half that exhibited at 21° C. In an initially carbon dioxide-free air stream the period shows a $Q_{10} = 2·5$. The reverse procedure, increasing the temperature from 11° C. to 21° C., reduced the period from 35·8 ± 1·4 min. to 12·6 ± 1·9 min. (Fig. 2). A lag of 30 min. occurred between the change in temperature and the resumption of the rhythm, and the peaks during the first hour at the higher temperature were somewhat irregular. This may account for the slightly shorter period and larger standard error.



Figs. 1–3. The effect of temperature variation on the rhythm of carbon dioxide output of an adult cockroach maintained in darkness and in either a carbon dioxide-free (1 and 2) or normal (3) air stream. For explanation, see text

In a stream of normal air, darkness and at 21° C. the period of the rhythm was 16·2 ± 2·0 min. (Fig. 3). On reducing the temperature to 11° C. carbon dioxide emission ceased for 45 min. and afterwards recommenced with a period of 47·3 ± 0·03 min. In normal air the period shows a $Q_{10} =$ 2·9 and again the amplitude was halved by the temperature reduction.

Removal of carbon dioxide from the air stream has no significant effect upon the period of the rhythm at 21° C., but at 11° C. the period is significantly longer in a normal air stream than in a carbon dioxide-free air stream. The rhythm was not inhibited or the period modified when insects maintained in an initially carbon dioxide-free air stream were illuminated with white light at an intensity of 3,000 lux.

These results contrast with those of Punt[3], who showed that *P. americana* lacks a rhythm of carbon dioxide emission, output being irregularly continuous in darkness, at 15° C. On the other hand, a rhythm of carbon dioxide output has been reported in the locust[4] in which the period was 2·5 min. in darkness, at 32° C. and in an initially carbon dioxide-free air stream. The locust exhibited the rhythm for only 24 hr. after shedding the last hopper skin. In contrast, the rhythm persisted for at least 4 days in the adult cockroaches used in this work. The period of the rhythm of emission of carbon dioxide in silk-worm pupæ has been shown to vary between 45 and 120 min. at 25° C.[5,6].

'Watery Stipe' of Cultivated Mushrooms

In a recent paper, Lindberg[1] described a transmissible disease of *Helminthosporium victoriae* in which the infective agent, not identified, caused a stunting of the mycelium. This condition could be transmitted to healthy cultures through contact, either by growing the two types together or by treating normal cultures with a suspension of macerated diseased mycelium in sterile water.

A very similar condition has now been found in the cultivated mushroom, associated with a disorder known to growers as 'watery stipe', 'brown disease' or 'La France disease'. The macroscopic symptoms are variable and include the death of immature sporophores which may turn brown. Different degrees of water-logging of the tissues, particularly of the stipe, also occur. In mild cases this appears as translucent streaks on the stipes, but in extreme cases the whole sporophore may be saturated and exude drops of liquid from the surface of the pileus. Sporophore distortions, such as elongated and bent stipes, are commonly found. Cropping is much below normal and ceases prematurely, this being the most serious aspect of the disorder to the commercial grower. The variable symptoms have made positive macroscopic identification impossible. The only consistent feature which has been discovered has been the degeneration of the mycelium, which is not always apparent from a cursory examination. If, however, fragments of the mycelium are plated out on an agar medium they will, if infected, produce weak, buff-coloured adpressed colonies without rhizomorphs. Healthy mycelium produces fluffy, white, more rapidly growing colonies with rhizomorphs radiating from the point of inoculation. The cells of the abnormal mycelium are shorter than normal and have a slightly swollen appearance. No other differences have been noted.

This mycelial degeneration has been transmitted to healthy cultures using methods similar to Lindberg's. With the double inoculation method, diseased and healthy cultures grow until their mycelia ultimately come into contact, but anastomoses between the hyphæ of the two colonies have not been seen. The coalescence of the two cultures is slow, as if there were antagonism between them, which is in marked contrast to the behaviour of two healthy colonies, where many of the rhizomorphs fuse. The growth of the healthy culture is usually weaker after coming into contact with the abnormal one; but there is no visible change in the appearance of the older mycelium. However, if this (originally healthy) mycelium is subcultured, its growth is abnormal.

Experiments with macerated mycelium have so far been confined to the use of suspensions containing fairly large fragments of mycelium which are capable of regeneration. Normal mycelium dipped in such a suspension grows at less than half the speed of mycelium dipped in suspensions of healthy mycelium or sterile water. Filtration to remove these mycelial fragments also removes the infective agent.

This investigation into the cause of the stunting of mushroom mycelium continues. Tests for the presence of bacteria have given negative results so far. The presence of a virus may be a possibility, although none has been found in fungi.

GENETICS

Self-Incompatibility System in Two Mexican Species of *Solanum*

So far the genetics of self-incompatibility has been described in only one species of *Solanum*, namely, *S. chacoense*[1]. It is an extremely variable species which occurs in north and central Argentine, Paraguay, Uruguay and south Brazil and now includes *S. caldasii*, *S. subtilius* and *S. jujuyense*[2]. *S. chacoense* has a one-gene, multi-allelic, gametophytic system of self-incompatibility similar to that which has been found in three other genera of the Solanaceae, *Nicotiana*, *Petunia* and *Lycopersicon*. Recently I have found that *S. megistacrolobum* has the same system as its sister South American species *S. chacoense* (in the press), whereas the two Mexican species, *S. ehrenbergii* and *S. pinnatisectum*, have a two-gene system.

Progenies of 20 plants were grown from reciprocal crosses between unrelated clones of each species. Siblings within each family were crossed in all directions and each sibling was also crossed reciprocally with its parents. In *S. ehrenbergii* one family produced four intra-sterile groups of plants, but the family from the reciprocal cross produced six such groups. In *S. pinnatisectum* both the families from the reciprocal crosses gave six intra-sterile groups each. Different groups in one family were cross-compatible with some and cross-incompatible with other groups. There were reciprocal differences in the results of crosses between different groups.

The results obtained in the two Mexican species are conspicuous for being quite different from those usually obtained in the *Nicotiana* type system. They are explained on the basis of the following assumption. The genetics of incompatibility is controlled by two independently segregating loci each with a series of multiple alleles. Pollen determination is gametophytic and there may be individual action or epistasis between the alleles of the two series. In the style there is individual action of S alleles. A pollen grain is incompatible on a style when either one or both of its two alleles (of two different series) are also present in that style. This system may prove to be of general occurrence in the Mexican species and limited to them. It has been found to occur also in *Physalis ixocarpa*[3], a native of Mexico and Central America. In contrast, the 1-locus system appears likely to be confined to the species of South America.

The occurrence of the 1- and 2-locus gametophytic systems of incompatibility in the same genus *Solanum* is of considerable evolutionary interest. There is enough evidence to suggest that the 1-locus *Nicotiana* type of gametophytic incompatibility, occurring in a large number of flowering plants, was the first system of incompatibility to develop, and evolved early in the evolution of angiosperms[4]. The sporophytic system[4] and the 2-locus gametophytic system[5] were both derived from this system. It also seems justifiable to assume that the 2-locus system was able to evolve in the Mexican diploid tuberous *Solanums* because of their geographical isolation as a result of the separation of North and South Americas.

Some of the biological forces which might have led to this genetic distinction between the species of the two groups can be suggested. Several investigators[6], on the basis of cytological studies, have concluded that the basic chromosome number in the family Solanaceae is 6 and not 12, which occurs in most of its species. If it is assumed that the present basic number 12 for a large part of this family has been derived by doubling of the original basic number six, very early in the evolution of this family, then the two S loci in the Mexican species are the result of the duplication of the original S gene. However, the possibility of a segmental interchange bringing about duplicate S loci cannot be ruled out.

Whatever might have been the origin of two S loci, in the beginning they must have caused self-compatibility due to the competition interaction between the S alleles in the pollen[7]. The restoration of self-incompatibility could then have occurred by different methods in the two groups of geographically isolated Solanaceous species. (1) In the South American species having a 1-locus system of incompatibility, the restoration of incompatibility occurred by a selection for the loss of function of one of the two S loci—a phenomenon which seems to have occurred in some of the known tetraploid species (for example, *Trifolium repens*[8]) of other families. (2) In the Mexican species having two S loci, the restoration of incompatibility occurred by a selection against competition interaction between the S alleles in the pollen, thus retaining two functional S loci. The absence of competition interaction in the diploid pollen of *Physalis ixocarpa*[8] seems to support this hypothesis. The reason why the Mexican group of *Solanum* species should have evolved differently in this respect than their sister species in South America is, however, not clear.

PSYCHOLOGY

Intelligence, Personality and Brain Rhythms in a Socially Isolated Community

SIGNIFICANT correlations between alpha rhythm in the electroencephalogram and ratings of the temperament variable primary-secondary function have been attributed to genetically determined individual differences in a central nervous excitability characteristic[1,2]. Since both alpha frequency[3] and vocabulary score[4] of the Wechsler Adult Intelligence Scale were reported as positively correlated with speed of perception, it seemed possible that performance on the Wechsler Adult Intelligence Scale might be influenced by primary-secondary function. This argument was supported by the finding in 34 subjects of a significant correlation ($r = 0{\cdot}51$, $P < 0{\cdot}01$) between alpha frequency and total score on the Wechsler Adult Intelligence Scale. Further analysis suggested that the Scale measures non-intellective in addition to intellective aspects of intelligence, and that the former possess a number of electroencephalogram correlates[5]. The fact that previous studies had failed to reveal correlations between alpha rhythm and intelligence was attributed to differences between the Wechsler Adult Intelligence Scale and other intelligence tests, and also to a sampling factor, it being proposed that the emergence of electroencephalogram correlates of non-intellective components of intelligence is dependent on the intellective and socio-economic homogeneity of the sample studied[6].

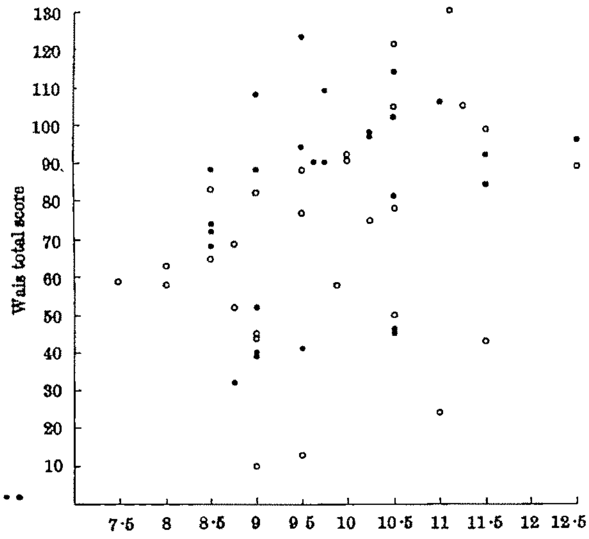

Fig. 1. Correlation chart showing relationship between intelligence score and alpha frequency. ●, Normal electroencephalograms; ○, abnormal electroencephalograms

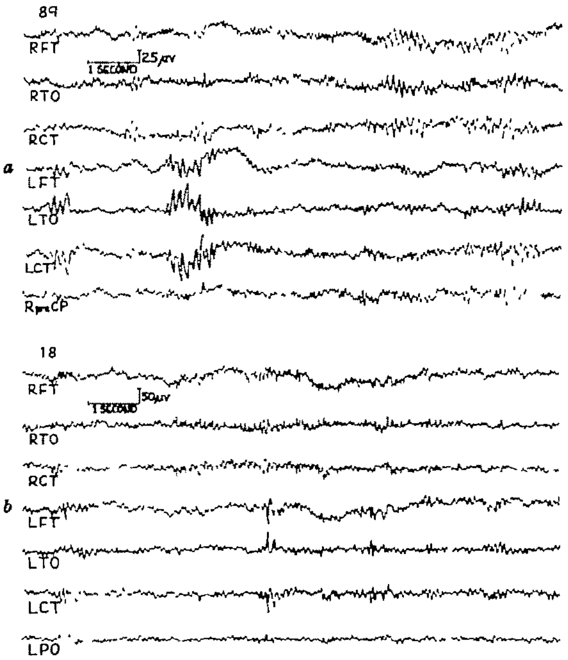

Fig. 2. Electroencephalogram abnormalities from two members of a socially isolated community, neither with any obvious neuropsychiatric symptom or known abnormal history: *a*, male, 64 yr., intelligence quotient not measured. Bilateral independent focal bursts from temporal lobes, more marked on left, frequencies mainly between 8 and 12 c./sec. with some theta rhythm; *b*, male, 56 yr., intelligence quotient 75. Focal spikes and sharp waves from left temporal lobe, also runs at 10–13 c./sec. and traces of theta rhythm. *R*, Right; *L*, left; *F*, frontal; *T*, temporal; *O*, occipital; *C*, central; *P*, parietal; pre*C*, precentral

As a test of these hypotheses we undertook an expedition to a remote region of South Africa to study a group of white labourers from a socially isolated community of long standing, the members of which are characterized by a high degree of behavioural uniformity and generally low intelligence. Electroencephalograms were recorded from 94 men and 2 women, of whom 55 men were also given the South African version of the Wechsler Adult Intelligence Scale. A number of other psychological tests was also applied.

Two important findings have now emerged. First, as predicted, alpha frequency is significantly correlated with total score on the Wechsler Adult Intelligence Scale ($r = 0{\cdot}34$, $P = 0{\cdot}01$, Fig. 1) and with raw scores from 5 Scale sub-tests, including vocabulary. These correlations were virtually unchanged with age held constant. Secondly, 49 (51 per cent) of the 96 subjects possessed abnormal electroencephalograms, all but one because of bilateral shifting foci from the temporal lobes, usually in the form of sharp waves, spikes, or bursts of activity ranging in frequency from 2–14 c./sec. (Fig. 2). These focal disturbances tended to be more prominent from the left side.

The correlations between alpha frequency and Wechsler scores support our hypothesis that given a homogeneous sample it is possible to identify a non-intellective component of intelligence which is related to a central nervous excitability factor. Detailed reports of distributions and interrelations between electroencephalogram variables, Wechsler scores and other psychological measures will be published elsewhere.

The finding of 50 per cent bilateral independent temporal lobe foci was quite unexpected, since this type of electroencephalogram abnormality is strong indication of organic disturbance in one or both temporal lobes, and is particularly common among certain epileptics[4]. Our sample contained one obvious case of epilepsy in the abnormal electroencephalogram group and two possibles in the normal group. There was no relation between any aspect of clinical history as elicited during interview and electroencephalogram abnormality, although no medical examination was performed. Family history revealed relatives with epilepsy in two cases in the normal electroencephalogram group and five in the abnormal group. This difference is not significant, although it seems that the incidence of epilepsy in this community is higher than in the rest of the Union of South Africa. Electroencephalogram abnormality was unrelated to age (Table 1), although the mean age of the abnormal group was significantly lower than the normal group (36 years as opposed to 43).

Table 1. AGE DISTRIBUTION: NORMAL AND ABNORMAL ELECTROENCEPHALOGRAMS

Age group	18–20	21–30	31–40	41–50	51–60	61–70	71–78
Normal electroencephalogram	0	8	8	16	8	4	2
Abnormal electroencephalogram	2	10	12	11	8	6	0

Foremost among possible explanations of the high incidence of electroencephalogram abnormality is birth injury, in view of the inadequacy of obstetric facilities in this region. In addition, malnutrition is common and may be critical, since we found that 36 per cent of a group of African infants with kwashiorkor exhibited temporal lobe foci[7]. Another possibility relates to the effects of inbreeding, known to have been prevalent in this community for many generations. In the words of the local district surgeon, "these people have remained a community within a community, merrily producing misfits of variation". Unfortunately, the need to secure the confidence of our subjects rendered it impossible to obtain any direct information concerning interfamilial marriages, but it was notable that a number of men were married to women with the same maiden name, and among the 91 male subjects showing neither filial nor fraternal relationship the total number of surnames was only 44, of which one occurred 11 times, one 8, three 5, two 4, three 3, and eight twice. This may be compared with 100 members of this Institute, among whom the total number of surnames is 90, of which three are repeated thrice and four twice. These figures support the contention that inbreeding has been prevalent among the population from which our experimental sample was drawn. That the high incidence of electroencephalogram abnormality may in some way be related to a genetic influence cannot therefore be excluded.

The mean intelligence quotient was 75, standard deviation 15, the distribution being skewed towards the lower end of the scale, with 15 mental defectives and 17 borderline mental defectives. However, although the mean intelligence quotient of the abnormal electroencephalogram group was 10 points lower than that of the normal electroencephalogram group, this difference is not significant ($t = 1{\cdot}29$, $P > 0{\cdot}20$). It is therefore unlikely that the low standard of intelligence and the high incidence of electroencephalogram abnormality are directly related consequences of a common factor.

Although distinctive personality attributes and mental symptoms have been commonly reported with electroencephalogram temporal lobe disturbances[6,8], we noted no such differentiating behavioural reactions among our normal and abnormal electroencephalogram groups. However, it should be stressed that the sample is peculiar in that it is drawn from a community which exhibits highly characteristic social traits, for example, an abject satisfaction in things as they are, an absence of individuality and self respect, a blissful self-satisfaction, and a stubborn resistance against any attempt to alter their way of life. It is possible that in such an undifferentiated and socially withdrawn community the development of mental symptoms as often observed elsewhere with temporal lobe foci would be either inhibited or moulded into the cultural framework.

We hope that later we will be able to revisit this region, both to extend the investigation in the neuropsychiatric sphere and to study younger generations, whereby we might evaluate the contribution of heredity to these findings. In the meantime, the observation that 50 per cent of a group which does not complain of fits or obvious neuropsychiatric disorder yet exhibits bilateral shifting foci from the temporal lobes merits careful consideration in relation to neuropsychology.

The expedition was undertaken with our Carnegie Mobile Psychological Laboratory, our colleagues being Miss B. Kirk-Cohen, Miss M. Oertel and Mrs. J. M. Nelson.

Syllabic 'Strategies' in Written Language

LANGUAGE, whether written or spoken, is one of the most sensitive indices of central nervous disorder; in a variety of neuropsychiatric states the speech and writing of the patient may be the main physical manifestation of disease. A technique of language analysis has been evolved with clinical needs in mind; but an attempt has also been made to provide a neurophysiological working hypothesis to account for the main empirical findings of the method.

The subject is asked to write 'about a page' on any topic of his own choice. The words written are then counted according to their length in syllables (S), and if p_S is the proportion of S-syllable words in the utterance, a quantity termed the 'avoidance' (A_s) is computed for each word-length. Avoidance is defined by the equation: $A_s = -\log p_s$.

The avoidances are then plotted against various simple functions of S. When it is found that A_s is an exact function of S, f(S), over the whole range of word-length employed, the sample is said to obey a pure 'strategy'. Not all, but about 25 per cent, of samples appear to show this phenomenon. Tables 1–4 contain examples of the four pure strategies so far encountered, which have been named and formulated as follows:

Linear: $A_s = k_1.S - A_0$ Logarithmic: $A_s = k'.\log S + A_0$
Quadratic: $A_s = k_2 S^2 - A_0$ Log. factorial: $A_s = k_f \log S! + A_0$

In these equations the k are slope-constants and the A_0 are intercepts on the A_s axis, usually with the signs indicated. A_0 is found to be zero in some utterances; in such cases the strategy requires only one constant to specify it and is therefore termed 'primitive'. In the Tables A_s are observed values while $A_s{}^*$ are values read off from a line drawn by eye through the points. Comparison of the two columns will indicate the closeness of fit of the strategy-equations to the data.

It seems that the brain tends to fall into a relatively limited number of patterns with respect to its spontaneous distribution of word-length. Some samples obey no obvious strategy; others show imperfect fit to one of the pure strategies; others can be described as obeying 'mixed' strategies which are combinations of pairs of the four pure types.

The likelihood that a subject will reproduce the same strategy on two separate occasions is still uncertain; but several subjects who have written two samples, separated by time-intervals ranging from minutes to days, in the absence of any apparent major change in physical or mental state during the interim, have shown stability of strategy apart from variations in the constants k and A_0. However, physicochemical agents which cause acute changes in the clinical state of the brain seem able to bring about 'switches' from one strategy function to another.

The findings can be explained by the following provisional hypothesis: The utterance of language consists in the conversion of specific patterns of neural activity corresponding to conceptual states (thoughts) into other patterns capable of eliciting appropriate motor activity from the motor effectors. This recoding process is assumed to involve several distinct information-handling operations, all of which must be completed before each unit of language can be uttered; hence the slowest operation will be rate-limiting for the overall process of uttering language units. The key postulate of the theory is that if the same operation remains rate-limiting for the whole of an utterance, the character of that operation will determine the strategy.

The assumption is also made that the avoidance (that is, statistical information) of S-syllable words is proportional to the amount of information handled by the neurones performing the operation which is rate-limiting for words of this length.

Now strategies are defined above in such a way that the *word* is the unit of language and syllables are sub-units. To specify a word it is necessary to specify both its component syllables and their order. Suppose that in a given utterance the rate-limiting process (for all word-lengths) happens to be that of ordering the syllables. A set of S syllables can be arranged in factorial S ($S!$) different orders, of which one is correct and must be selected. The information required for a discrimination of this complexity is, ideally, proportional to $\log S!$. On the above assumptions, the avoidance should be given by: $A_S = K.\log S!$. This is the equation of a primitive log factorial strategy.

In a similar way it may be imagined that other operations (such as the formulation of ideas) are required in the generation of an utterance and could become rate-limiting, so giving rise to other strategies. The constants A_0 are not explained by the theory in its simple 'ideal' form but may be due to the imperfection of the brain as a communication mechanism. Mixed strategies and strategy-switches are explained by natural extensions of the theory. A fuller account of this work is in preparation.

The collection of material has been greatly helped by a grant from the Theodore Chapin Beebe Fund. I am indebted to Dr. Hick of the Cambridge Psychological Laboratory and to Dr. Russell Davis of the Medical Psychology Laboratory for their constructive criticism and advice.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, February 15

Society of Chemical Industry, Pesticides Group (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. T. E. Tomlinson: "Mode of Action of Dipyridyl Quaternary Salts as Herbicides".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.1), at 6 p.m.—Dr. Albert Parker: "World and National Energy Resources". (First of three Cantor Lectures on "The Fuel and Power Industries and National Prosperity". Further lectures on February 22 and 29.)

Institute of Metal Finishing (at the Northampton Polytechnic St. John Street, London, E.C.1), at 6.15 p.m.—Mr. T. K. Aiken: "Complexones in Metal Finishing".

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, W.C.2), at 6.30 p.m.—Wing Commander E. W. Anderson: "Inertial Navigation Systems".

Tuesday, February 16

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. K. Ridgway. "Problems of Early Steam Engine Design".*

Institution of Electrical Engineers, Supply Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Soviet Control Engineering Progress" opened by Mr. R. E. Clark.

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. C. H. Gray. "Non-Pancreatic Aspects of Diabetes Mellitus".* (Eleventh of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on February 18, 23, 25 and March 1.)

Society of Visiting Scientists (at 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "Radioactive Fall-out". Chairman: Prof. A. Haddow, F.R.S. Speakers Mr. J. F. Loutit, Dr. W. G. Marley and Prof. K. Mather, F.R.S.

Wednesday, February 17

Physical Society, Colour Group (at the Institute of Ophthalmology, Judd Street, London, W.C.1), at 3.30 p.m.—Dr. J. D. Moreland: "Colour Discrimination, Field Size, Field Position and Acceptor Populations". 4.15 p.m.—Miss J. Cox: "Colour Vision Defects Acquired in Diseases of the Eye".

British Glaciological Society (joint meeting with the Royal Meteorological Society, at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. Herfried Hoinkes (Austria): "Studies in Glacial-Meteorology in the Antarctic, 1957".

Eugenics Society (at Manson House, 26 Portland Place, London, W.1), at 5 p.m.—Mr. Eliot Slater: "Galton's Heritage" (Galton Lecture for 1960).*

Institute of Physics, London and Home Counties Branch (at 47 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting, followed by Prof. S. Tolansky, F.R.S.: "The Microstructures of Surfaces".

Institution of Electrical Engineers (at Central Hall, Westminster, London, S.W.1), at 6 p.m.—Prof. M. G. Say: "Electrical Machines" (Faraday Lecture).

Society of Chemical Industry, Corrosion Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. Roger Parsons: "Adsorption on Electrodes and Its Relation to the Rate of Electrode Processes".

Royal Institute of Chemistry (at King's College, Strand, London, W.C.2), at 6.30 p.m.—Dr. W. G. S. Parker: "Rocket Propellants".

Thursday, February 18

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. P. Dean: "Vibrational Spectra of Diatomic Chains"; Mr. D. W. Pashley: "A Study of the Deformation and Fracture of Single Crystal Gold Films of High Strength Inside an Electron Microscope".

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. A. G. Darnley. "Petrology of Some Rhodesian Copperbelt Orebodies and Associated Rocks".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. P. J. Hilton: "Group-like Structures".

Institution of Electrical Engineers, Utilization Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. B. E. A. Vigers and Mr. R. O. Fletcher: "Electricity in the Manufacture of Hydrogen Peroxide".

University College (in the Embryology Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. E. Evans-Pritchard: "Religion and the Anthropologist".* (First of two Special University Lectures in Anthropology. Further lecture on February 25.)

Royal Aeronautical Society (at the Institution of Mechanical Engineers, 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. D. Best: "Missile Control Problems".

British Computer Society, London Branch (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. R. G. Hitchcock: "The Development of the Use of a Computer for Production Control".

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Dr. T. F. Davey: "Some Recent Chemotherapeutic Work in Leprosy" with a Discussion on some of the Problems Involved in Clinical Trials.

University of London (at Wye College, Wye, Ashford, Kent), at 8.15 p.m.—Prof. M. M. Swan: "New Light on Growth".*

Friday, February 19

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. J. A. Fraser Roberts: "Medical Genetics".* (Further lectures on February 26, March 2, 4, 11 and 18.)

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5.15 p.m.—Symposium on "Space Navigation".

Institute of Physics, Non-Destructive Testing Group (at 47 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. P. Schagen: "Electroluminescent Image Intensifiers".

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. E. B. Knott: "Organic Chemistry of Colour Photography".

Society for Analytical Chemistry, Microchemistry Group (at the Postgraduate Medical School, Ducane Road, London, W.12, at 6 p.m.—Annual General Meeting. 7 p.m. (joint meeting with the Biological Methods Group)—Scientific Papers.

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. J. Z. Young, F.R.S.: "Eyes, Colours and Shapes".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Health Education, Human Anatomy and Physiology—The Principal, Borough Road College, Isleworth, Middlesex (February 22).

University Demonstrator in the Department of Animal Pathology, School of Veterinary Medicine, to undertake teaching and research in veterinary parasitology—Dr. J. W. Millen, Department of Anatomy, The University, Downing Street, Cambridge (February 26).

Assistant Experimental Officer (with an ordinary degree or diploma in agriculture or botany)—The Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian (February 27).

Assistant Lecturer or Lecturer in Animal Husbandry in the Faculty of Veterinary Science—The Registrar, The University, Liverpool, quoting Ref. CV/T (February 29).

Lecturer or Assistant Lecturer in the Department of Chemical Engineering, The Houldsworth School of Applied Science, to specialize in separation processes, fluid dynamics or thermodynamics and chemical kinetics—The Registrar, The University, Leeds 2 (February 29).

Physicist or Biophysicist, to assume responsibility for an Electron Microscope—The Secretary, The Institute of Ophthalmology (University of London), Judd Street, London, W.C.1 (February 29).

Research Assistant in the Department of Physics, for work concerned with the fundamental study of electro-luminescence and related processes in single crystal phosphors—The Registrar, The University, Hull (February 29).

Imperial Chemical Industries Research Fellows in Chemistry, Biochemistry, Physics, Engineering, Chemotherapy and related subjects—The Secretary, Academic Council, The Queen's University, Belfast (March 1).

Assistant Lecturer (Terminable) in Botany—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (March 5).

Assistants (2) one in Mathematics and one in Statistics; and a Research Fellow in Mathematics—The Secretary of University Court, The University, Glasgow (March 5).

Lecturer in Radiochemistry—The Registrar, The University, Leeds 2 (March 5).

Lecturer or Assistant Lecturer in Physics—The Secretary and Registrar, The University, Southampton (March 5).

Henry Skynner Senior Student in Astronomy—The Secretary, Balliol College, Oxford (March 12).

Lecturer or Assistant Lecturer (with an interest in applied plant physiology) and a Research Demonstrator in the Department of Agricultural Botany—The Registrar (Room 22, O.R.B.), The University, Reading (March 14).

Lecturer or Assistant Lecturer in Crop Husbandry at Makerere College (University College of East Africa)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 15).

Milne-Munro Research Fellow (graduate wishing to carry out research in agriculture or cognate subject) at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 15).

Chair of Applied Mathematics in the University of Malaya (Singapore Division)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 31).

University Demonstrator in Metallurgy—Dr. F. B. Kipping, University Chemical Laboratory, Lensfield Road, Cambridge (March 31).

Senior Lecturer (with appropriate qualifications and experience) in Botany at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong and London, April 5).

Associated Electrical Industries Fellow for Research in the Department of Physics—The Secretary-General of the Faculties, The Old Schools, The University, Cambridge (April 30).

Chair of Biochemistry in the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong and London, April 30).

Lecturer in Physiology (Histology)—The Secretary of University Court, The University, Glasgow (April 30).

Biochemist (male, with experience of work in the steroid field) at the Sheffield Centre for the Investigation and Treatment of Rheumatic Diseases—The Group Secretary, Sheffield No. 1 Hospital Management Committee, "Lyndhurst", Nether Edge Hospital, Sheffield 11.

Coconut Agronomist (with a university degree in agriculture or botany with experience in the design and analysis of factorial experiments on crops, and preferably experience of experimental work on tropical tree crops) in the British Solomon Islands Protectorate, to supervise existing experiments and to establish a Coconut Research Centre—The Director of Recruitment, Colonial Office, London, S.W.1, quoting Ref. BCD.63/45/04/T.

Lecturer in the Department of Biochemistry—The Secretary, University College, Gower Street, London, W.C.1.

Master to teach Physics and Chemistry in the Sixth Form, with some Scholarship work in one of these subjects—The Headmaster, Blundell's School, Tiverton, Devon.

Senior Technician (male or female)—The Director, Blood Transfusion Service, Roby Street, Manchester 1.

Staines Medical Research Fellow (not exceeding 35 years of age, of English birth, and preferably with a registrable medical qualification), for research in Oxford in one of the medical sciences, such as anatomy, biochemistry, clinical medicine, pathology, pharmacology or physiology—The Rector, Exeter College, Oxford.

Theoretical Physicist, and an Experimental Physicist, for duties which will involve instruction in undergraduate and graduate courses—The Chairman, Department of Physics, Assumption University of Windsor, Windsor, Ontario, Canada.

COMMONWEALTH EDUCATION AND DEVELOPMENT

IN an adjournment debate on aid to under-developed territories on December 17, Mr. A. E. Cooper said that technical assistance is one of the greatest contributions that Great Britain can make, possibly exceeding in importance what we can do in the way of finance. He referred particularly to the assistance we can give in agriculture, and suggested that we should be more concerned as to the manner in which such technical assistance can be given and the right type of technical colleges provided. Mr. Cooper also believes that there are too many organizations through which assistance can be given, and that the Colombo Plan or similar regional organizations provide the best basis and are more effective than the United Nations. Mr. J. Hall, who stressed also the bearing of a healthy balance of payments on the amount of assistance Britain can give, likewise suggested that our most important contribution is in the field of technical assistance. Here the real difficulty is the supply of technicians and skilled labour available, and he believes that the Government could do more to encourage the training of technicians for service overseas, particularly on Government service. The provision of sufficient qualified teachers, too, is a major difficulty in establishing schools, technical colleges and universities overseas, particularly while service overseas does not rank for pension, and Mr. Hall thinks that the Government could help here by making it possible for such service to count for pension when teachers returned to teach in Britain.

Sir Edward Boyle, Financial Secretary to the Treasury, in welcoming the debate, commented that more interest is being taken in Britain and other Western countries in helping the less developed territories than ever before. Expenditure from United Kingdom public funds on economic and technical assistance to overseas countries and territories has risen from about £75 million in 1957–58 to about £100 million in 1958–59, and is likely to reach £150 million in the current financial year, exclusive of military assistance, emergency expenditure, relief measures and such like, which amount to roughly £30 million a year, while it is estimated that of £300 million a year gross of private investment overseas, about half goes to the less-developed countries. Our bilateral assistance goes mainly and normally to Commonwealth countries: contributions to multilateral organizations go in support of their programmes of assistance to member countries. He believes that there is scope for building up the international institutions in this field, and Sir Edward referred in particular to the Colombo Plan, the International Monetary Fund, the International Finance Corporation and the International Development Association, to the last of which, if acceptable plans come to fruition, the United Kingdom will be subscribing about £50 million. Sir Edward welcomed the reference to agriculture and said that it would be impossible to over-rate the importance to the West of the success of India's second Five Year Plan.

This debate followed a discussion on the same subject initiated by the Marquess of Reading in the House of Lords on December 10 which, however, was concerned chiefly with the Colombo Plan and the countries of South and South-East Asia. Lord Reading himself discussed especially the question of teachers, as well as the importance of greater efforts for more adequate and widespread teaching of English in these countries; he also stressed the importance of the quality of the people who are sent out to render technical and other assistance. Lord Lansdowne, the Joint Parliamentary Under-Secretary of State for Foreign Affairs, just returned from the Colombo Plan Conference in Indonesia, referring particularly to technical assistance, said that up to June 1959 the United Kingdom had provided 2,600 training places in Britain for Colombo Plan students, and 360 United Kingdom experts had taken up assignments in Asia. Moreover, there are now in British universities and training colleges some 40,000 students from overseas, and we have already committed ourselves to £150 million under the Colombo Plan, of which nearly £30 million was spent in the year ended June 1959. Like other speakers in the debate, Lord Lansdowne referred to the need for more generous treatment of those who volunteered for teaching service overseas and for ensuring that their opportunities for promotion are not prejudiced thereby. The Earl of Lucan referred to the bearing on the problem of the new scholarships to be provided under the Commonwealth Scholarships Bill, and Lord Salter stressed the importance of careful choice of appropriate institutions, such as the World Bank, for the provision of capital assistance.

Lord Home, in replying on the debate, suggested that there is no field in which scientific and technical knowledge can pay higher dividends than that of agricultural and farming methods in the Asian countries. Referring to the improvement in recent years in international markets, he agreed on the necessity for stability in the prices of the primary products of Asian countries, and reminded the House that our ability to increase our aid must arise out of the improvement in our balance of payments. It is because of the increase in reserves that Britain has been able to double its subscription to the International Bank, and to increase by 50 per cent its subscription to the International Monetary Fund, while simultaneously its contribution from public funds to economic and technical assistance rose from £75 million in 1957–58 to more than £100 million in 1958–59 and has probably increased by a corresponding amount during the past twelve months. Lord Home agreed as to the importance of technical assistance and of appropriate arrangements being made by local authorities and other employers of teachers to ensure that teachers do not suffer in their careers on return to Britain from service overseas. He believes that, for the time being, regional bodies offer the best means of dealing with the problem, and that the time is ripe for a concerted effort in Western Europe to raise the standard of living in the under-developed countries.

In spite, however, of the reference to the Commonwealth Scholarship Bill, there was no reference in either debate to the Commonwealth Education Conference, although the report of the Conference* dealt specifically with the training of teachers, the supply of teachers for service in countries of the Commonwealth other than their own and to technical education, and specific recommendations are made in the report to deal with these problems. Because the Commonwealth is a new experiment in human relationship, founded on a belief in the worth and dignity of the human individual and a recognition of the value of freedom and co-operative action, education is fundamental to the strength and stability of the Commonwealth, and to social justice and human dignity which must be its inspiration. There is an obligation on those with more highly developed educational facilities to help their fellow members.

The expansion of educational systems in all the countries of the Commonwealth requires new teachers on an unprecedented scale, and all countries, whatever their stage of educational development, need to expand and improve their facilities for teacher training. While some awards made under the Commonwealth Scholarship and Fellowship Plan are likely to be in the field of teacher training, in the long term the training of teachers on the scale required to meet normal needs must be achieved by the efforts of the countries themselves. The Conference Committee which dealt with this subject recommended that the teacher-training assistance provided should be carefully directed to secure the greatest possible benefit in proportion to the resources employed, and that some of the additional places now offered should be reserved for advanced or supplementary courses and only a relatively small proportion used exceptionally for initial training. Some of the funds should be used to enable teacher-training staff in the more advanced countries to assist the development of teacher-training in other countries.

Provision to give experience in training institutions to teacher-training staff from countries with less well-established systems of education is also recommended, and some members of teacher-training staffs in colleges receiving Commonwealth students from other countries should be enabled to visit and gain experience of the countries from which these students are drawn. To overcome the widespread shortage of candidates sufficiently equipped both technically and academically for immediate training as technical teachers, the Committee suggests the provision, where necessary by special courses, of a technical background for young people who have an adequate standard of general education. As a development of major importance, it also recommends that a proportion of the places to be made available should be allocated to training in the teaching of English as a second or later language.

The report stresses the importance of arrangements being made to receive students suitably on arrival and to induct them into their new surroundings and way of life, and of efforts, both before and after their arrival in the host country, to determine whether they need any special instruction in the language of their host country. Countries benefiting from the assistance offered by the United Kingdom should normally bear the cost of travel of their students, but a certain sum should be allocated from United Kingdom funds to assist the travel of students from relatively small and isolated territories. Adequate maintenance allowances are regarded as an integral feature of assistance towards training, and the cost of maintenance should be fully met from any grants made, even if this involves reducing the number of places originally offered by the United Kingdom.

A further Committee of the Commonwealth Education Conference considered the extent to which the countries of the Commonwealth could help each other to meet their needs for training teachers and staff who will train teachers, and the arrangements for providing such assistance. The numbers of primary school teachers required cannot be estimated with accuracy, but clearly many thousands will be required during the next four or five years, mainly from the countries concerned; but to assist these countries to train this large number, there is an immediate need for some 400 or 500 posts to be filled in their teacher-training institutions. Well over 1,000 teachers a year are needed for secondary schools, and about 200 teachers a year for technical schools, while universities throughout the Commonwealth are in need of staff, often in highly specialized subjects. The greatest needs are in Africa.

Already more than 2,500 teachers a year leave the United Kingdom for service in other Commonwealth countries and the Government is to make every effort to increase this number. Canada, Australia and New Zealand made definite offers of assistance at the Conference, and both India and Pakistan hope to encourage their teachers to serve in other Commonwealth countries. In its report the Committee recommended that, to ensure that assistance should be applied at the most fruitful and effective points, governments should concentrate on filling what might be described as key posts in countries where there is a shortage of teachers and that, where appropriate, the filling of such key posts should be facilitated by special allowances to teachers, assessed for the individual appointment. The interests of teachers serving abroad should be safeguarded in such matters as housing, children's education, adequate recognition of teaching service abroad, promotion prospects, re-employment and secondment rights, superannuation and re-settlement on return. The Committee also recommended that the question of establishing a Commonwealth Education Service should be examined, and that a small organization should be established to provide information about vacancies and the availability of staff for service abroad. Steps should also be taken to promote a climate of opinion which will recognize service abroad as a professional asset, and consideration should be given to the secondment of teachers between Commonwealth countries or between regional authorities in one country and another.

---

* Commonwealth Relations Office. Report of the Commonwealth Education Conference. Pp. 65. (Omnd. 841.) (London: H.M. Stationery Office, 1959.) 4s. net.

The Committee which considered the extent to which the countries of the Commonwealth could help each other to meet their needs for developing education and training in technical subjects, including training in industry, and the arrangements for providing such assistance, recognized that the training of technologists and technicians in adequate numbers is a serious problem, but pointed to some measures which could be taken immediately. A substantial number of additional places for Commonwealth students will be made available in the universities and technical colleges of the United Kingdom and Canada, and India and Pakistan are willing to offer similar facilities. The Committee strongly recommended that the interchange of scientists and technologists, which is of lasting benefit, should be encouraged and that all countries offering scholarships, other awards or facilities for education, training or research should devote a good proportion of the awards or facilities to technical education. More places should be provided in universities and higher technological institutes in Commonwealth countries for students from small countries which have no such facilities, and the governments of small Commonwealth countries should consider the co-operative establishment of regional technical teacher-training colleges. Postgraduate scholars in science and technology should be encouraged to take part-time teacher-training courses, and the Committee also directs attention to the need for close and continuous attention to the supply of books and periodicals, as well as to the value of consultation with the appropriate professional bodies regarding qualifications awarded by technical institutions so as to ensure a high and uniform standard of attainment.

Normally, arrangements for mutual aid in technical education should be made bilaterally between the countries concerned, and every country should set up a permanent organization to supervise the detailed operation of mutual assistance; but a small information centre established in London might provide information about facilities for technical education and sources of advice available in the Commonwealth. Finally, the Committee recommends that efforts be made to increase mutual assistance by providing opportunities for training and experience in industry from people from Commonwealth countries, and that technical education should receive a full share of all the various kinds of financial and other assistance resulting from the Conference.

The report of the Commonwealth Education Conference estimates that the arrangements agreed at the Conference will involve new expenditure of at least £10 million during the next five years, and it recommends the establishment of a committee in London composed of a representative of each member country of the Commonwealth, with appropriate arrangements to represent the interests of the Colonial territories and provided with a small administrative unit. For the rest, the strength of the new arrangements rests in men and women and the cultivation of personal relationships; and the administrative arrangements proposed are designed to assist the normal channels to flow more freely. Apart indeed from the stimulus given by the Conference to the flow of ideas and exchange of experience, this stimulus to the interchange of scholarship, either in science and technology or in other fields, is of as vital import to the effectiveness of the aid given by the West to the under-developed territories as is the stimulus given to education itself. Both alike should broaden the mutual understanding upon which effective aid must rest and remove suspicions and distrust. Now that the Western governments are seeking to co-ordinate their plans for economic aid to the under-developed countries, education assumes an increasing importance not simply in the matter of technical assistance but also in the establishment of institutions which will enable assistance, whether financial or economic or social, to be given efficiently and swiftly to the greatest effect.

MECHANICS IN THE MIDDLE AGES

The Science of Mechanics in the Middle Ages

By Marshall Clagett. (University of Wisconsin Publications in Medieval Science, Vol. 4.) Pp. xxix + 711. (Madison, Wisconsin: University of Wisconsin Press, 1959.) 8 dollars.

It has long been customary to consider the Middle Ages as a period without any importance for the rise of modern natural science. The Greek contributions were duly studied; then came a blank of several centuries, commonly designated as the Dark Ages, and the story began again with Galileo, whose work seemed to arise out of nothing. The scholastic ideas on natural science were deemed wholly barren and, if ever mentioned, only to be ridiculed.

A marked change in this unfruitful and essentially unhistorical approach was brought about at the beginning of this century by Pierre Duhem, French historian of science, who in a series of brilliant works assumed an entirely new attitude towards the scholastic ideas on natural science in general and on mechanics in particular. He showed that several important notions and results, which always had been considered as typical of the revival of learning in the 16th and 17th centuries, had to be dated back some two or three centuries. His investigations were continued in Europe by C. Michalsky, Anneliese Maier and others. At the same time there arose in the United States a new centre of medieval studies at the University of Wisconsin. There Marshall Clagett notably distinguished himself by penetrating studies in the field of medieval mechanics. The book mentioned above, together with an earlier volume on medieval statics published some years ago by him in collaboration with Ernest Moody ("The Medieval Science of Weights", Madison, Wisconsin, 1952), may be considered (except for new discoveries) the definitive exposition of our present knowledge of the subject. The huge volume is divided into four parts, the first of which contains the essential contents of the former volume with some important supplements. Parts II and III are devoted to kinematics and dynamics respectively and Part IV is an extremely useful summary of the whole subject of medieval mechanics. After an introduction the author generally gives an English translation of the documents at issue, followed by a lucid commentary and by the original text.

The most important subjects treated are: (1) the work of Gerard of Brussels, the importance of which was appreciated some years ago by the author and discussed by him in vol. 12 of *Osiris* (73–175; 1956); (2) the contribution of the scholars of Merton College, Oxford, especially Thomas Bradwardine, William Heytesbury, Richard Swineshead and John of Dumbleton, towards the kinematics of uniformly accelerated motion; (3) the application of plane geometry to kinematics in the graphical method, resulting in a geometrical proof of the so-called Mertonian rule for uniformly accelerated motion, formerly called Oresme's rule by Duhem; (4) Bradwardine's dynamic law of movement, which, though not valid, contributed essentially to the rise of mathematical physics; (5) the theory of impetus and its application in the explanation of the acceleration of free fall and of the movement of celestial bodies; (6) the daily rotation of the Earth, as discussed by Buridan and Oresme, who both advanced strong arguments in favour of it, without, however, bringing themselves to accepting it.

The way in which all these subjects are treated by the author deserves our admiration and assures him a prominent place among the authorities on medieval mechanics. E. J. DIJKSTERHUIS

PHYSIOLOGY OF REPRODUCTION

Reproduction in Domestic Animals

Vol. 2. Edited by H. H. Cole and P. T. Cupps. Pp. xi+451. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 13 dollars.

FORMERLY the physiology of reproduction was studied mainly in small laboratory animals, but, with the increasing economic importance of the larger domestic animals, during the past two decades much work has been done in this field. The second volume of the book on "Reproduction in Domestic Animals" emphasizes the differences which exist between species in the details of their reproductive process.

Six of the eleven chapters, each written by an expert on the subject, deal with the male: spermatogenesis by Ortavent, biochemistry by Mann, libido and storage of semen by Rowson, insemination by Almquist, and the fowl by Lorenz. These present a most comprehensive review of recent literature on the subject. Among many interesting subjects dealt with are calculations of the daily sperm production, species differences in semen characteristics, factors affecting libido and semen quality, the deep-freezing of semen, differences in the technique of insemination in different species, and the effects of œstrogens on the cock. Among the other chapters, one on nutrition by Moustgaard is an important contribution, for among other things it gives a very good account of the nutrient requirements for fœtal development in different species, a subject which has hitherto received but little attention. The effects of under-feeding of the various food constituents, including vitamins and minerals, on the development and viability of the offspring as well as on the functions of the reproductive organs are also described.

In another chapter, by Clegg and Ganong, other environmental factors affecting reproduction in different species are outlined. These include the effects of variation in daylight hours, temperature and humidity together with 'social stimuli', such as that of the sexual display in birds. The physiology of the female fowl is described by Van Tienhoven, and this includes sections dealing with behaviour in mating and broodiness; the effects of different hormones are also reviewed. A chapter on anatomical and physiological factors affecting fertility by Mixner deals with intersexuality and such things as testicular and ovarian hypoplasia, hernias, cystic ovaries, and embryonic mortality. Hart and Osebold describe the infectious diseases of bacterial, virus and protozoan origin.

The book should be most useful to agriculturists and veterinarians, as well as to those engaged in human medicine, for many of the experimental results reviewed are fundamental to the physiology of mammalian reproduction. J. HAMMOND

HISTORY OF BIOLOGY

A History of Biology to about the Year 1900

A General Introduction to the Study of Living Things. By Dr. Charles Singer. Third and revised edition. Pp. xxxvi+580. (London and New York: Abelard-Schuman, Ltd., 1959.) 50*s.* net.

WHEN writing or talking about biology there are two schools of thought, namely the one which maintains that to try to learn or understand the history of the subject is a waste of time, and the other which holds that to understand any subject one must appreciate and know its beginnings and its development. These two differing attitudes can be reconciled by the assumption that biology only found itself as a science about 1850 and what went before is 'irrelevant and immaterial'.

To this reconciliatory suggestion Dr. Singer has produced a stimulating reply in the third and revised edition of "A History of Biology", which is based on the thesis that "the man of science must work backwards for a space . . . for unless we adopt a wide historical outlook we shall find ourselves unable to grasp the nature of the great problems which we are discussing".

After an introduction in which the claims of the historical approach are advanced, the book is divided into three parts. The first part, entitled "The Older Biology", treats aspects of the subject from Hippocrates to Harvey and the circulation of the blood in 1628. In the second section, the "Historical Foundations of Modern Biology" are laid by the development of experimental method in the works of Bacon and Descartes, and followed through the ideas of taxonomy and evolution into the immediate post-Darwin era. There is a number of topics of general interest in the third section such as "Cell and Organism", "Development of the Individual", etc., each of which is examined from a historical point of view.

It is therefore an ambitious book, but as an introduction to the study of living things (which is the sub-title) it seems to me to fall a bit short of the mark. For example, Dr. Singer has chosen his end-point at about 1900. This is sixty years ago, and since that time biology has progressed so quickly and so far that the average reader and television viewer will wonder where he can find the links between this book and the science he sees and hears about him every day. It is realized that to write an up-to-the-minute history of biology is beyond the scope of any man, but when the first edition of this book was published in 1931 it was only thirty years out-of-date, whereas, although additions have been made, it is now sixty years behind the times.

It is proper that a 'history' should contain the names of many people, places and things. But it is bewildering to someone seeking an introduction to find so many things, dates and people on each page and my reaction was to begin to skip certain paragraphs as contributing too little to the main theme.

Nevertheless this book is not simply a compendium and it clearly is a work of scholarship and insight. I found it interesting, stimulating, and in places almost exciting. It is well written and illustrated with much to give to both professional and amateur biologists, and if it has its faults they spring more from the dual task which Dr. Singer has set himself than from any deficiencies in style or material. A. R. GEMMELL

MYCENÆAN AND CLASSICAL GREECE

The Annual of the British School at Athens

No. 52, 1957. Pp. viii+264+50 plates. (London: The British School at Athens, 1959.) 63*s*. net.

THIS is an interesting number. J. Boardman writes on "Early Euboean Pottery and History", and re-opens the question whether the "Chalcidian" ware of the sixth century B.C., assigned by fashionable archæologists to Italiote workshops, was in fact made in Chalcis after all. Euboic letter-forms show, he thinks, close contact between Euboea and Phoenicia in the eighth century B.C. The notorious early war between Chalcis and Eretria for the Lelantine Plain is dated by most scholars around 700 B.C., and supposed to have ended in the triumph of Chalcis. Boardman points out, however, that possession of the plain, necessary to Chalcis, matters little to Eretria, and that Eretria apparently suffered no material setbacks between 800 and 600. I wonder whether one can go farther, and put the end of the war, the Chalcidian victory and the rise of Chalcidian ware all well into the sixth century. This is a very stimulating paper.

A. Andrewes considers early Hellenistic lists of *patrai* in Kamiros. At this date, they were subdivisions of local tribes, and represented a complicated modification of the earlier gentile *patrai*.

V. Karageorghis identifies a Mycenæan vase-painter working in the Levant, who favoured chalices and bowls among shapes, and animal protomae among ornaments.

R. A. Higgins re-examines the Aegina Treasure, now in the British Museum, which recent scholars have dated at about 800 B.C. He demonstrates that, however it reached Aegina, it is mostly, perhaps entirely, Middle Minoan, of about the seventeenth century, and close in style to the treasure of Mallia. His arguments seem conclusive and important.

G. E. Bean and J. M. Cook continue their survey of the Carian Coasts. They retail evidence for their view that classical Cnidus was at Burgaz, near Datça, and that the classical Triopion, at Kumyer near by, had an enormous sea-wall. They also examine the large walled city of Theangela, in their view a creation of Mausolus. But they attribute the large landward wall of Iasus to the late-fifth-century Persian rebel, Amorges, the ally of Athens. Moreover, they believe that at Meropis, on Cos, the Athenians set up their own copy, in Attic lettering, of the famous monetary decree of about 449 B.C., because they had an Athenian station there. The argument is interesting, although we could not have inferred from the decree that coins with the legends "KOION" and "KOS" would soon afterwards be struck at Meropis. Indeed, the wording of the decree seems to give a monopoly of striking to the mint at Athens. This article sturdily and refreshingly rebuts various pedantic dogmas of Louis Robert.

T. E. Jones, L. H. Sackett and C. W. T. Eliot survey the Dĕma, the famous westward-facing wall between the Athenian and Thriasian Plains, and conclude that it dates from the years of panic after Chaeronea (338 B.C.). They note that its plan uses the "indented trace", here closely resembling the landward wall of Iasus, which they date (p. 182) to the fourth century. They were unaware, of course, of Cook and Bean; and it is amusing to see these various dates put forward in one annual.

The number also includes some stray linear *B* tablets from Cnossus, published by John Chadwick, the last harvest of Wace's campaigns at Mycenae, R. Hope Simpson's arguments for a Mycenæan Messene and Sinclair Hood's account of a tower and wall of *c*. 300 B.C. near the Zafer Papoura cemetery at Cnossus. HUGH PLOMMER

BIOCHEMISTRY OF HUMAN GENETICS

Human Biochemical Genetics

By Dr. H. Harris. Pp. viii+310. (Cambridge: At the University Press, 1959.) 37*s*. 6*d*. net.

NO subject in biology is of greater current interest than genetics, and the genetics of human beings is becoming of immense practical importance. It is ironical that most of our knowledge of human genetics comes from a very few fields—in particular blood groups and biochemistry. Several excellent treatises on blood groups are available, but this book by Dr. Harris is the first comprehensive text on the latter field.

In his introduction Prof. L. S. Penrose rightly remarks that the publication of A. E. Garrod's classic "Inborn Errors of Metabolism" marked the beginning of a revolution in genetics. Yet its fruits are slow to ripen. From the last edition of Garrod's book in 1923 until Dr. Harris published his previous work "Introduction to Human Biochemical Genetics", twenty years passed, during which time very little progress was made in human biochemical genetics. Since then a flood of new and fascinating work has appeared—for example, that on the glycogen storage diseases, galactosæmia and the chemical differences between the hæmoglobin variants. The present volume is thus much more than a new edition of Dr. Harris's previous book. It is a good deal longer and well up to date. The chapters deal in succession with a historical sketch, simple genetics, the metabolism of amino-acids and of carbohydrates, the abnormal hæmoglobins, the blood groups, plasma proteins, miscellaneous conditions and the problem of gene action. The last chapter is in many ways the weakest, though it is undoubtedly the most difficult subject to handle. The other chapters are all of an even and high standard. In matters of fact the book is remarkably accurate ; in matters of interpretation it is lucid and well balanced.

The author has somewhat cramped his style by omitting most of the subjects which are speculative, poorly understood, or which cannot be given a firm chemical basis. For example, little mention is made of favism, or of the ability to taste phenylthiocarbamide, or to smell hydrogen cyanide. Population genetics is only briefly treated. This gives the reader the impression of a neatly ordered but restricted field, and the book is therefore less stimulating than it might have been if some of the more provocative themes had been included.

One of the most encouraging aspects of the work described here is the remarkable possibility of cure of the symptoms of some of the inherited diseases. This emphasizes the point that whatever the eugenic problems of our remote descendants, the challenge of our own time is primarily a therapeutic one.

It is a pleasure to handle a book which is so well printed and well bound. The format is the Cambridge University Press's best—well-spaced type on good paper, with contrasting founts for genetic symbols, and clear uncramped figures. The index is reasonably full. It is very well worth the price, and should be in the library of every department of genetics. P. H. A. Sneath

COTTON AND GENETICS

The Application of Genetics to Cotton Improvement

By Sir Joseph Hutchinson. Pp. viii+87. (Cambridge: At the University Press, 1959. Published in association with the Empire Cotton Growing Corporation.) 15*s*. net.

THIS slim volume of eighty-six pages is based on a number of lectures given by Sir Joseph Hutchinson at the North Carolina State College, with some additions from recent work at the Namulonge Station, of which he was director.

The comprehensive title of the book is scarcely applicable to the restricted range of topics discussed. The reader is led to expect a scholarly appraisal of the methods employed and results obtained in other countries and by other workers. He will be disappointed.

The work is divided into six sections, which deal respectively with cotton relatives, the origin and spread of the Old World cottons, the origin and spread of New World cottons, the pattern of evolution in cotton-breeding systems, and the improvement of African cottons.

Discussion of problems implied by the title has to be confined within the limits of forty pages. This must be the author's excuse for a mode of treatment lacking in historical perspective, and which promulgates numerous one-sided opinions on questions still acutely controversial.

Much space is given to a discussion of the theory of the recent origin of the New World tetraploid cottons put forward by the author and his colleagues, R. A. Silow and S. G. Stephens. When first put forward in 1947, this theory was greeted with almost unanimous incredulity. The author now summarizes recent cytological and archæological evidence which at last consigns the theory to respectable burial, although he does not formally reject it himself.

The work of Manning and Sir Joseph Hutchinson on the response of Uganda cotton to selection is described. It is shown that by using a selection index in relatively inbred material, a yield advance of the order of 4 per cent per annum was achieved over eight generations of selection.

This technique is important enough to find a place in cotton breeding, but will probably not come into general use unless it can be combined with the mass pedigree system, and with the recent extensions and modifications of this used by Knight in the Sudan. These comprise selfing alternated with panmixis ; transfer of genes, and transfer of gene complexes by alternate generations of back crossing and selfing.

Nowhere is it stated that the increase in yield obtained in Uganda was in a cotton with the minute yield of 1,000 lb. of seed cotton per acre—approximately one-third of that currently obtained in more favoured countries.

The references to breeding policy in Egypt are unfair and misleading. The brilliant work of Balls and his colleagues in Egypt in almost every branch of science bearing on both yield and quality has been a source of inspiration to cotton workers for nearly a half-century. To omit the name of the inventor of cotton technology is inexcusable ; to misrepresent his policy is both mischievous and irresponsible.

It is clear that Balls was never unmindful of either yield or quality. He has written books on both subjects. He tried to strike a balance between the two ; he "bred to dollars". Although it receives no mention, the work of Hancock, who subjected hundreds of progeny samples to a small-scale spinning test both for the direct evaluation of quality and for an assessment of genetical purity, is of far-reaching importance since it concerns the very future of cotton as an agricultural crop.

Peruvian workers will note with raised eyebrows the statement that Peruvian Tanguis is "fairly primitive by the standard of most cotton growing countries, being a perennial". In point of fact Tanguis has a low node number, and is no more a perennial than Sea Island, Upland or Egyptian cotton. Far from being primitive it is a highly selected and productive cotton much appreciated on the world market.

Apart from these criticisms, and others for which space is lacking, the book contains much valuable information on the development and evolution of cultivated cottons. It is authoritative when the author refers to material well known to him, and it brings up to date the account given by him and his colleagues in their well-known work "The Evolution of *Gossypium*". S. C. Harland

POTASSIUM–ARGON AND RUBIDIUM–STRONTIUM AGES OF SOME GRANITES FROM BRITAIN AND EIRE

By PROF. J. L. KULP, DR. L. E. LONG and C. E. GIFFIN
Geochemical Laboratory, Lamont Geological Observatory, Columbia University, Palisades, New York

DR. A. A. MILLS*, DR. R. StJ. LAMBERT and DR. B. J. GILETTI

AND

DR. R. K. WEBSTER
Analytical Chemistry Branch, Atomic Energy Research Establishment, Harwell, Berkshire, England

THE development of modern techniques of isotopic age determination makes possible an absolute definition of the geological time-scale. The scale in common use was constructed by Holmes[1,2] and placed the beginning of the Upper Cambrian at 450 million years ago. He was handicapped, however, by uncertainties in the age and stratigraphic assignment of the samples then available ; and subsequent investigators[3–9] and Holmes himself (personal communication) have found it necessary to suggest that the scale should be lengthened.

The most radical revision was that of Mayne *et al.*[8], who suggested that the age of the Upper Cambrian should be nearer 650 million years. This time-scale has already been criticized on general grounds[10,11], but in view of the importance of the revision it was also considered desirable to check some of their results. In an earlier paper[10] it was concluded that the evidence for this extended time-scale rests largely with the measurements made by Mayne *et al.*[8] on British granites. The present article gives some new data obtained for the same rock units by using the isotope dilution technique for argon determinations, and by making independent age determinations by the rubidium–strontium method.

The work at Oxford of Mayne *et al.*[8] began as an investigation, under the direction of Prof. L. R. Wager, into the ages of British granites and related intrusions. In the British Isles, two major sets of granitic intrusions have unusually well-defined stratigraphic relationships connected with the Caledonian and Hercynian earth movements. No subsequent alteration of these intrusions has occurred, with the exception of late-stage magmatic effects[12,13]. The ages obtained by the potassium–argon and rubidium–strontium measurements on the micas of these intrusions should therefore reflect the actual date of intrusion and crystallization of these magmatic bodies.

Among the Caledonian intrusions are the 'granite' masses of Shap, Leinster and Creetown (the latter listed by Mayne *et al.*[8] as "Cairnsmore of Fleet" ; the specimens analysed come from a large granite dyke at Creetown which is probably related to the Cairnsmore of Fleet intrusive) which all cut a folded Ordovician–Silurian series. This series is overlain by Upper Devonian–Lower Carboniferous sediments, which were deposited on the folded and eroded Lower Palæozoic strata.

The adamellite of Shap cuts Ordovician strata ; but the metamorphic aureole surrounding the Shap affects Upper Silurian (Ludlovian) strata, which are the highest beds involved in the pre-intrusion folding[14]. The basal Carboniferous nearby, which is of Lower Dinantian age, contains Shap pebbles[15]. The age of the intrusion is thus post-Ludlovian and pre-Carboniferous. Further, it is probable that it should be assigned to the Downtonian (the transitional Siluro–Devonian stage) or the Lower Devonian on account of general petrological and structural evidence, which, however, is inconclusive.

In Leinster, the upper limit of age is provided by Ordovician deposits and the lower by Upper Devonian. The Creetown granite cuts Upper Silurian strata ; but no lower age limit is definable. In both cases it is generally assumed from petrological similarities that these masses were intruded at the same period of igneous activity as the Shap adamellite.

The Hercynian granites of Britain occur in Devon and Cornwall, and cut a folded Devono–Carboniferous series which is unconformably overlain by continental sediments conventionally referred to the Permian and Trias. The Dartmoor granite cuts a folded series containing Viséan, Namurian and Lower Westphalian fossils[16], though in the immediate neighbourhood of the granite only Viséan fossils are known[17]. Thus, while the Dartmoor granite is almost certainly post-Lower Westphalian, Lower Stephanian strata in Somerset are affected by the same fold system[18] and it is therefore probable that the granites are of latest Stephanian or Permian age. The Land's End granite is correlated with the Dartmoor granite on geochemical and petrological grounds.

The analytical results are given in Table 1 (potassium–argon determinations at Lamont) and Table 2 (rubidium–strontium determinations at Oxford and Harwell). The analyses were all made on samples of biotite separated at Oxford, except for the Leinster granite which was collected by one of us (J. L. K.), with the co-operation of Mr. M. V. O'Brien, director of the Geological Survey of Eire. Samples were further purified by the analysts separately, so that it is not possible to compare analytical details between laboratories. All potassium analyses, however, were made on carefully split aliquots of the final preparations used for the argon measurements.

The isotope dilution method using enriched argon-38 as 'spike' was used for all argon determinations. Over the period occupied by this work. five different spike sets were employed. Analyses of the Massachusetts Institute of Technology standard biotite by four spike sets are given in Table 3. These results agree with measurements reported by four other laboratories on this standard to within 1 per

Parentheses indicate potassium analysis on identical material at Oxford, by flame photometer. All others by Ledoux and Co.

cent (P. M. Hurley, personal communication). The coefficient of variation of radiogenic argon measurements at Lamont, based on many duplicate analyses over the past two years, is less than 2 per cent. The absolute uncertainties for samples in this age-range are estimated to be ± 2 per cent, based on the performance of the spike calibration system and the results shown in Table 3. A somewhat higher error is assigned to the samples run with spike ($5{\cdot}19 \times 10^{-4}$ cm. mercury) as this was calibrated indirectly by runs on micas of known radiogenic argon content. The details of these experimental procedures are being given elsewhere[19].

The potassium analyses were performed (with one exception) by Ledoux and Co., Teaneck, New Jersey, using a flame photometric method which has been shown to be reproducible with a coefficient of variation of 1–2 per cent based on blind duplicates. Their results agree with those of the University of Minnesota Rock Analysis Laboratory and isotope dilution analyses at the Lamont Geochemical Laboratory to within 2 per cent. Thus it may be assumed that the individual argon-40/potassium-40 ratios have a coefficient of variation of 3 per cent in this work. Additional inter-laboratory calibrations up to mid-1957 are given by Baadsgaard *et al.*[20] which show a coefficient of variation of only 3–4 per cent on the argon-40/potassium-40 ratios among all contributing laboratories (including Lamont).

The Dartmoor sample 1-*B* was analysed for potassium in the Oxford laboratory by C. McInnes and is believed to be accurate to at least 2 per cent, based on inter-laboratory calibration standards. The argon analysis was done on the identical material. An insufficient quantity was available for analysis by Ledoux and Co.

The potassium–argon isotopic ages were calculated using the decay constants indicated in Table 1. The average age was computed by calculating weights for the individual determinations from their probable errors. The Land's End granite sample was so small that a larger uncertainty is necessarily assigned to the potassium–argon determination of this specimen; but the agreement with the Dartmoor ages is such that the intrusions could have been emplaced at about the same time. The Shap, Creetown and Leinster granites have the same age within the experimental errors. The biotite from the Leinster granite is intimately chloritized and may have suffered slight loss of argon, but the difference between the average muscovite and biotite ages can also be comprehended by experimental error.

Determinations of the age of these micas by the rubidium–strontium method have been made independently at Oxford and at Harwell (Table 2). Both laboratories employed isotope dilution techniques throughout, using enriched rubidium-87 and either strontium-84 or strontium-86 tracers supplied by the Atomic Energy Research Establishment, Harwell. The Harwell techniques have already been described[21]. At Oxford the rubidium and strontium contents, and strontium isotopic composition, of each specimen were determined on a Metropolitan-Vickers *MS 5* solid-source mass spectrometer; analytical details will be discussed in a subsequent paper.

The absolute error in the radiogenic strontium-87/rubidium-87 ratios determined at Oxford is estimated at ± 3 per cent, based on the agreement with the Harwell results and with samples the ages of which were also determined at Lamont (by B. J. G.) and elsewhere. The errors quoted for the Harwell determinations were calculated from the spreads of the various duplicate analyses. A half-life of $(4{\cdot}7 \pm 0{\cdot}1) \times 10^{10}$ years is used for rubidium-87 [22]. The rubidium–strontium ages for the Caledonian (Shap and Creetown) granites agree quite closely with the potassium–argon data reported in Table 1, and again indicate that the two intrusions were contemporaneous. The

* Indicates radiogenic component.

rubidium–strontium values are much closer to the present potassium–argon ages than to those of Mayne *et al.*[8].

Should the $5 \cdot 0 \times 10^{10}$ year half-life of rubidium-87 (commonly in use at present) be employed, the value found for the average age of these rocks would increase by 6 per cent, and would agree with potassium–argon dates reported in Table 1 to within 2 per cent. The error in the reported rubidium–strontium ages would have to be about 25 per cent for these to agree with those of Mayne *et al.*[8].

The Hercynian data from all sources do not differ as much as the Caledonian dates, but agreement between the potassium–argon and rubidium–strontium measurements reported here is particularly close. Agreement with the Mayne *et al.*[8] dates would necessitate a 10 per cent error in the rubidium–strontium ages given here.

The age data for the Dartmoor granite should be considered in relation to a concordant uraninite age of 290 ± 10 million years for the Cornwall mineralization[23].

On Holmes's Scale *B*[2] the Carboniferous–Permian boundary was 203 million years and the Siluro–Devonian boundary 313 million years. The measurements reported here thus support suggestions for an extension of that scale. A revised time-scale based in part on some of these measurements has been published elsewhere[24]. The discrepancy between the potassium–argon results reported here and those of Mayne *et al.*[8] (which are given in the last column of Table 1) poses an analytical problem which has not yet been solved.

This research has been supported at Lamont by the Research Division, U.S. Atomic Energy Commission, under Contract *AT*(30-1)-1669. Grants from the Department of Scientific and Industrial Research and the Colonial Development and Welfare Organization have supported the research at Oxford. Enriched isotopes for the rubidium–strontium work were supplied by the Atomic Energy Research Establishment, Harwell.

RELATIONSHIP BETWEEN THE RATE OF FALL-OUT AND THE CONCENTRATION OF STRONTIUM-90 IN HUMAN DIET IN THE UNITED KINGDOM

By DR. J. D. BURTON, G. M. MILBOURN and DR. R. SCOTT RUSSELL

Agricultural Research Council Radiobiological Laboratory, Letcombe, Wantage, Berkshire, and
Agricultural Research Council Field Station, Compton, Berkshire

IF the long-term consequences of strontium-90 in world-wide fall-out are to be assessed it is essential to determine the degree to which the contamination of human diet depends on the rate of fall-out as opposed to the cumulative total in soil. In an earlier publication it was concluded that the contamination of milk, especially, depended largely on the rate of fall-out[1]. The very tentative nature of the assessment was, however, emphasized. A more precise assessment is now made possible by a more detailed study of the content of strontium-90 in human diet in the United Kingdom which was made in 1958[2] and by additional results of field experiments[3,4].

More than 40 per cent of the milk produced in the United Kingdom is now sampled every two weeks and bulked according to a statistical plan before analysis. During 1958 it was found that the ratio of strontium-89 to strontium-90 in milk during the summer months was more than five times that in the cumulative deposit and at least half of that in the current deposition in rainfall. Because of the shorter half-life of strontium-89 this ratio decreases by a factor of two every seven weeks; thus the effective delay period between the deposition of strontium-90 and its appearance in milk was 1–2 months. Evidence of the importance of recently deposited strontium-90 in determining the contamination of other foods was also obtained.

Although such observations support the conclusion that the contamination of diet is at present largely determined by the quantity of fall-out deposited in the recent past, they do not enable the magnitude of the contribution from the cumulative total in the soil to be assessed. The ratio of strontium-89 to strontium-90 observed in milk is equally compatible with the contrary views that all the strontium-90 in milk was deposited some two months previously, or that it was equally divided between very recent and very old material; other evidence, however, makes the latter conclusion appear unlikely. If the situation is to be adequately interpreted, it is necessary to solve the equation:

$$C = xDp + yDt \qquad (1)$$

where C is the quantity of strontium-90 in the material under investigation, Dp and Dt are respectively the deposition during the life of the plant from which the strontium-90 was derived and the cumulative deposition in the soil, and x and y are proportionality factors.

For reasons previously discussed[1], it has been concluded that the most satisfactory method now available for solving this equation is to compare the observed levels of strontium-90 from world-wide fall-out in food products with experimental measurements of absorption from the soil. Since 65 per cent of the strontium-90 in diet in the United Kingdom comes from milk and milk products[2] the solution of the equation for this material is of primary importance.

Absorption of Strontium-90 from the Soil

A series of field experiments[3,4] has been in progress for three years, to provide information on the extent to which strontium-90 will be absorbed by crops grown under normal agricultural conditions on representative soil types in the southern part of Great Britain; the results are therefore considered to be applicable to England and Wales. Strontium-89 has been applied as a spray to the surface of the soil which is then cultivated to a depth of 4, 7 or 11 in. before crops are sown. Since the application of carrier-free strontium-89 as a fine spray can be regarded as simulating the deposition of radioactive strontium in rain, these experiments should form a reasonably satisfactory basis for assessing the extent to which plants will absorb strontium-90 which is deposited in world-wide fall-out. When ryegrass, or a ryegrass-clover pasture mixture, is grown under these experimental conditions, it is found that absorption is considerably reduced when the soil has been cultivated to the greatest depth. Thus the relationship between the quantity of strontium-90 in soil and the content of plants will change slowly with time as the strontium-90 penetrates more deeply into the soil. Furthermore, it has been observed in some experiments that irrespective of the depth of cultivation the ratio of strontium-90 to calcium in plants may decrease with the passage of time. Two calculations of the relationship between the quantity of strontium-90 in soil and the content of pasture plants have therefore been attempted:

Calculation A: The immediate situation. To estimate the situation likely to occur soon after strontium-90 has been incorporated in the soil, the results have been used for the entire season's crop when land has been cultivated to 4 in. after contamination. The distribution of strontium-90 down the soil profile caused by this method of cultivation is comparable to that now observed from world-wide fall-out in undisturbed soil.

Calculation B: The long-term situation. Deeper penetration of strontium-90 into the soil must be considered. This calculation is therefore based on the average results obtained at the end of the growing season when grass has been grown on land cultivated to 4, 7 and 11 in. after contamination.

Since the extent to which strontium-90 is absorbed from the soil is influenced by the availability of calcium in the soil, the results of the different experiments have been weighted according to the fraction

Table 1. ESTIMATE OF MEAN RATIO OF STRONTIUM-90 TO CALCIUM EXPECTED IN PASTURE GRASSES UNDER FIELD CONDITIONS IN ENGLAND AND WALES FROM SOIL CONTAINING 1 mc./km.^{2}

'Available' soil calcium (m.equiv./100 gm.)		> 15	10–15	5–10	< 5	Country-wide mean
Fraction of total area		0·53	0·19	0·24	0 044	
Experimental results : Mean Sr-90/Ca ratio ($\mu\mu$c./gm.) in ryegrass	Calculation *A*	0·70	1·26	2·72	8·01	
	Calculation *B*	0·49	0·67	1·90	3·75	
Contribution to country-wide mean Sr-90/Ca ratio ($\mu\mu$c./gm.)	Calculation *A*	0·37	0·24	0·65	0·35	1·61
	Calculation *B*	0·26	0·13	0·46	0·17	1 01

Calculation *A*, the situation shortly after contamination ; Calculation *B*, the long-term situation

of the total agricultural land in England and Wales which is of similar calcium status[5]. The country-wide mean values for the ratio of strontium-90 to calcium expected in pasture grass assuming that the soil contains one millicurie of strontium-90 per km.^{2} have been derived (Table 1). The content of plants has been expressed as the ratio of strontium-90 to calcium and not as a concentration or as the percentage absorbed.; as these latter quantities will vary, depending on yield and on the environmental conditions during the growing season, they are not satisfactory bases for the calculation of the resulting levels in milk.

Fraction of the Strontium-90 in Milk which is attributable to Absorption from the Soil

Since the field experiments were carried out in the southern part of Great Britain, attention is here confined to assessing the probable extent to which absorption from soil is responsible for the contamination of milk in England and Wales. It has been shown that the quantity of strontium-90 deposited in different parts of the country varies closely with rainfall and measurements of the content of rainwater have been made[6,7]. The mean cumulative deposition of strontium-90 per km.^{2} of land throughout the country can therefore be derived as 11·5 mc. in the middle of 1958. The analysis of soil samples from representative undisturbed pastures in different parts of the United Kingdom shows that on average approximately 65 per cent of the estimated cumulative deposition remained in the upper 4 in. of soil[2] and it is known that little strontium-90 had penetrated below this level. It therefore appears reasonable to assume that some 65 per cent of the deposition as estimated by measurements of rainfall was accessible to plants in the upper soil layers ; the mean level of strontium-90 per km.^{2} of soil in pastures in England and Wales in July 1958 was therefore 7·5 mc.

It is thus possible from the data in Table 1 to estimate the mean ratio of strontium-90 to calcium expected in pasture plants as a result of absorption from the soil. In calculating the resultant levels in milk, account must be taken of the discrimination factor of 0·10–0·14 against strontium relative to calcium in their passage from the diet of cattle to milk[8], and of the fact that an appreciable fraction of the total diet of cattle is relatively uncontaminated (for example, concentrates) ; this latter fraction has been assumed to be 20 per cent. The ratio of strontium-90 to calcium expected in milk as the result of strontium-90 entering plants from soil has been calculated on this basis and compared with the levels observed in the country-wide survey of milk during 1958 (Table 2). In the calculation it has been assumed that the discrimination factor against strontium relative to calcium is 0·14 ; since the observed range of values is 0·10–0·14 some over-estimate of the contribution of the soil may have been made.

The calculation suggests that at the present time (calculation *A*) about 20 per cent of the strontium-90 in milk is due to absorption from the soil ; furthermore it appears that, if the present cumulative deposit were more thoroughly incorporated in the soil (calculation *B*), it would lead to a level in milk of approximately 12 per cent of that now due to world-wide fall-out. Since the quantity of available calcium in soil varies between different parts of the country, variations in the magnitude of the contribution from soil are to be expected. Separate calculations have therefore been made for the eight zones into which England and Wales have been divided for the study of radioactivity in milk[2]. It appears that the present contribution of absorption from the soil may range from 10 to 33 per cent of the observed levels in milk.

In this assessment no allowance has been made for the effect of future applications of lime to agricultural land. When land is of low calcium status the addition of lime significantly reduces the uptake of strontium-90. Some estimate of this effect can be made from the results of field experiments[3,4], and it has been calculated that future additions of lime at normal agricultural rates to land of low calcium status would reduce the average absorption of strontium-90 from soil throughout the country by approximately 10 per cent.

The proportionality factor x in equation 1 has been estimated (Table 3) by dividing the difference between the observed and calculated values for milk (Table 2) by the rate of fall-out during the year[7] ; y has been estimated by multiplying the country-wide mean levels in herbage (Table 1) by the discriminatory factor in the transfer of strontium and calcium to milk.

Conclusions

The results of the present calculation for the long-term situation may be compared with the earlier assessment based on 1957 data. The two estimates

Table 2. COMPARISON OF THE MEAN LEVEL OF STRONTIUM-90 IN MILK PRODUCED IN ENGLAND AND WALES DURING 1958 WITH THAT EXPECTED IF STRONTIUM-90 WAS ABSORBED ONLY FROM THE CUMULATIVE DEPOSIT IN SOIL

	Ratio Sr-90/Ca $\mu\mu$c./gm	Percentage of observed value
Observed value from world-wide fall-out, 1958	6·84	
Calculated levels for absorption from soil		
Calculation *A*, immediate situation	1·35	20
Calculation *B*, long-term situation	0 84	12

Table 3. Proportionality Factors for the Estimation of Levels of Strontium-90 in Milk by the Equation $C = xDp + yDt$

Proportionality factor	Calculation *A*, immediate situation	Calculation *B*, long-term situation
x, Dependent on rate of deposition ($\mu\mu$c. Sr-90/gm. Ca per mc./km.^{2} deposited per annum)	1 0	1·1
y, Dependent on cumulative deposition ($\mu\mu$c. Sr-90/gm. Ca per mc./km.^{2} cumulative total in the soil)	0 23	0 14

C, Content of milk: $\mu\mu$c. Sr-90/gm. Ca; Dp, rate of deposition: mc./km.^{2}/annum; Dt, cumulative total in the soil: mc./km.^{2}; x and y, proportionality factors.

are not entirely independent since the results for some half the field experiments used in the present calculation provided the basis for assessing absorption from the soil in the earlier study. Confidence in this approach is, however, encouraged by the fact that the values for the proportionality factor y are little different in the two calculations (0·14 and 0·16). The present estimate for proportionality factor x is less than two-thirds of that previously estimated. This is considered to be due partly to removal of strontium-90 from the soil not being taken into account in the earlier calculation and partly to the fact, to which attention has been directed elsewhere[2], that during 1958 the contamination of milk and other agricultural produce did not rise as greatly as the rate of fall-out. It appears probable that this was because the higher rainfall in that year caused a larger fraction of the deposition to be removed from the plants in wash-off.

Although the present calculations are based on the fullest data now available, their imperfections are clearly apparent. The extrapolation to the country-wide situation from a limited number of field experiments is an inescapably inaccurate procedure. Moreover, alternative methods for utilizing the present data are possible though on balance they appear less reasonable. However, two independent lines of evidence, namely the ratios of strontium-89 to strontium-90 in milk and the present calculation, both indicate the importance of recent deposition as opposed to the cumulative total in determining the contamination of milk. While the calculations here presented have been made with respect to the situation in England and Wales only, the general similarity of the ratios of strontium-89 to strontium-90 in milk throughout the United Kingdom[2] suggests that they provide a reasonable guide as to the situation in the whole country.

It has previously been emphasized that local agricultural conditions and climate may cause wide variations in the direct contamination of vegetation[1]; thus the contribution of the cumulative total to the mean level in diet is likely to vary both between different regions and between seasons in any one locality. The present assessment is advanced solely as the best approximation now available for a single country. It is, however, of interest that comparable evidence of the importance of the rate of fall-out in determining the level in diet is available from elsewhere. The ratios of strontium-89 to strontium-90 in milk produced in the United States and in Canada during 1958 have been shown to be similar to those in the United Kingdom[9]. This does not imply that the situations are identical, since the average ratio of strontium-89 to strontium-90 in rain during the same period appears to have been somewhat higher in the United States than in the United Kingdom. However, it is evident that the effective delay period between the deposition of strontium-90 and its appearance in milk was still relatively short; suggestions[10] that the quantity of strontium-90 in milk in North America is determined by the cumulative total in the soil are not compatible with these observations. Finally, it may be noted that recent evidence from a number of sources suggests that the contamination of wheat and rice[2,11,12] and of green vegetables[2] with strontium-90 also depends largely on the extent of the recent deposition.

PROGRESS OF CANCER RESEARCH

THE thirty-sixth annual report of the British Empire Cancer Campaign* is a massive volume of more than 600 pages dealing with the component reports from the institutes and individual investigators supported by the funds provided by the Campaign—£637,000 was spent on research in 1958. To attempt to summarize the results or even the trends of all the investigations in progress is no easy task; some idea of the current themes can be gained by simply cataloguing the different branches of work which are being pursued at the various institutions (see last year's review in *Nature*, 182, 1547; 1958).

The researches described in the Report can be grouped into three categories: (*a*) clinico-pathology of cancer; (*b*) radiation-therapy and physics and radiobiology; (*c*) carcinogenesis and carcinogens, chemotherapy and the cytology, genetics, biochemistry and demography of cancer.

Only a few of the hundreds of investigations can be referred to in the present review.

The lung cancer–cigarette smoking problem, after the initial impetus given to its solution by the admirable papers of Doll and Hill, has dwindled into attempts to reproduce the postulated carcinogenic effect of cigarette smoking, using mouse and rat tissue, and into the detection or identification of carcinogens in smoke condensates.

---

* British Empire Cancer Campaign. Thirty-sixth Annual Report covering the year 1958. Part 1: The Chairman's Statement and the Accounts. Pp. ii+43. Part 2: The Scientific Report of the Researches undertaken by the Central Organization and its Autonomous Councils in the United Kingdom, and by some of its Affiliated Organizations Overseas. Pp. lviii+636. (London: British Empire Cancer Campaign, 1959.)

Blacklock, continuing the studies initiated by the late Sir Ernest Kennaway, has been inoculating fractions of tobacco smoke condensate into the lungs of rats ; these substances were phenols, wax, neutral fractions, carboxylic acids, nornicotyrine, nicotyrine, metanicotine, myosmine, nornicotine, neutral fraction minus hydrocarbons, hydrocarbons and bases minus nicotine. The histological effect induced by tobacco tar in the lungs of rats and guinea pigs has been to induce squamous metaplasia of the bronchial mucosa, sometimes with papillomatous changes.

Peacock, at Glasgow, has studied the incidence of lung adenocarcinoma in series of mice housed in a soot-free room and also in a room exposed to the unfiltered air of central Glasgow ; he concluded that, "there is no evidence to support the idea that atmospheric pollution is a major factor in the ætiology of adenocarcinoma of the lung in C_3Hf mice. Even in animals with no detectable soot in their lungs, tumours occurred at least as frequently as in those whose lungs had obvious deposits of soot". At the same centre polycyclic hydrocarbons present in diesel and petrol exhaust fumes have been identified and assayed: these were, 3 : 4-benzopyrene, 3 : 4-benzofluorene, tetracene (naphthacene), pentaphene, 1 : 2 : 3 : 4-dibenzopyrene, 11 : 12 benzofluoranthene, 1 : 2 : 9 : 10-dibenzotetracene, 1 : 2 : 4 : 5-dibenzopyrene and 1 : 12 : 2 : 3-dibenzoperylene.

Lasnitski, in Cambridge, has been studying the effect of cigarette smoke condensates on organ cultures of (i) human fœtal lung and bronchial tissues and (ii) the bronchi of newly born pigs.

At Leeds, Green and his collaborators are confirming Wynder's results using cigarette smoke condensate applied to mouse skin ; so far as the experiments go, they show that cigarette smoke contains a weak carcinogen.

The effect has been tried of adsorbing a powerful carcinogen (9 : 10-dimethylbenzanthracene) on carbon particles and exposing mice to an atmosphere containing such an artificial soot ; from the development of superficial papillomas it was concluded that the skin apparently elutes the carcinogen from the carbon, but that this elution does not take place in the subcutaneous tissues, nor do the mice breathing air loaded with the carbon-adsorbed carcinogen develop lung cancer. This result could suggest that the carbon, or soot, might conceivably have protective properties by the adsorption of carcinogens.

Among the latest additions to the catalogue of carcinogens is ordinary 'Cellophane', first discovered by Oppenheimer to induce sarcoma in rats after subcutaneous implantation. Horning and Alexander, and also Price, Geffree and Taylor, find that the tumour-producing potency depends very largely on the area of 'Cellophane' inserted under the skin ; pieces of 9 cm.^{2} gave 46 per cent sarcomas, 2·25 cm.^{2} gave 19 per cent sarcomas and 0·56 cm.^{2} gave 0 per cent ; filter paper (2·25 cm.^{2}) or micro cover glasses gave 0 per cent tumours. In Horning and Alexander's experiments with Visking sausage tubing, 2 cm. × 2 cm. gave 60 per cent sarcomas in rats ; 1 cm. × 1 cm., 20 per cent and 0·5 cm. × 0·5 cm., 0 per cent. Oppenheimer, in 1955, had reported that if the 'Cellophane' is first perforated before implantation the incidence of tumours is very considerably reduced. Developments in this field of 'physical carcinogenesis' are awaited with much interest.

The more recent chemotherapeutic agents used for cancer treatment are *nor*-HN2(di-2-chloroethylamine), amino-chlorambucil, melphalan, busulphan (myleran) and glucosaccharo : 1 → 4 : lactone. Unfortunately, these drugs have as yet had only a very limited degree of success, partly perhaps because the therapist usually tries them on advanced cases, and as a result of his caution he is likely to weight the chances against the treatment.

But if the cure of cancer by drugs is still in its infancy, the alternative approach to the disease, namely, prevention, is at least receiving more support. Doll and Hill came to the conclusion that in Britain four-fifths of lung cancers in men are inescapably connected with cigarette smoking : the Report quotes a parallel statement from Oettlé and co-workers who are engaged in demographic studies of cancer in South Africa. These workers write : "The figures provide further evidence of the influence of manner of life on susceptibility to particular cancers and would justify the conclusion that about two-thirds of white (that is, peoples) cancer deaths are inherently preventable by modification of manner of life and environment. The nature of such modification is for the most part not yet defined".

Oettlé *et al.* base their conclusions on the following data : the incidence of cancer in a population of half a million Bantu Africans was studied for a 3-year period and compared with U.S. White, U.S. Negro and Danish populations, age and sex being taken into account. It appears that urbanized Bantus have a total cancer-rate half that of U.S. Whites and Negroes, that the Bantu have a much higher œsophageal and liver cancer-rate (males) and a higher cervix-rate. Rural Bantu have a lower œsophageal and lung cancer-rate, but a higher sinus and foot melanoma-rate compared with urban Bantu.

The Cape Coloured population, which is of mixed White, Hottentot and Malay origin, shows a lower œsophageal and a higher lung and stomach cancer-rate than the Bantu ; the manner of life of the Cape Coloured peoples resembles much more closely "that of Western races and their tumour incidence tends to resemble that of the American negro more than the South African Bantu".

Burrell, at the Cape Bantu Cancer Registry, reports that in the south-eastern regions of the province the natives have a very high and rising incidence of cancer of the œsophagus and that it appears to be more frequent among the well-to-do ; he states, "Thirty-two instances of œsophageal cancer in man and wife have been recorded as well as other combinations of members of the same kraal household. A strong case is developing for environmental carcinogenesis". In the Bantu of the Mozambique region, Prates and colleagues report that liver cancer is exceedingly common whereas carcinoma of the œsophagus is unknown ; skin cancer is very common and the general distribution of sites of cancer is very different from that in the Bantu of Johannesburg and the Transkei.

Another approach to the problem of cancer in Africa is the Kampala Cancer Registry, set up by the British Empire Cancer Campaign at Makerere College to study the incidence of cancer in Uganda. It has now been in operation for several years and is beginning to show practical results outside statistics. A method for the treatment of Kaposi's sarcoma by intra-arterial injection of nitrogen mustard has proved to be a major advance in the treatment of this lesion, which is common in the area. One of the difficulties of the Registry has been the lack of adequate demographic data as a background to its own figures, and its committee appears to have stimulated a pilot survey of three small areas already completed, and of a survey of one whole country proposed as part of the current census of Uganda, which will result in knowledge of the age structure of the population in detail unusual in a tropical country. A similar registry has begun work in Jamaica, but has so far not reached the stage of reporting results. The value of surveys of this type may well be immense. As death-rates from malnutrition and infections decrease, tumours become more important in tropical areas, and it is well to be pre-warned as to what kinds of tumour are likely to become common: they present a very different pattern from those of Great Britain.

The most interesting development in the virus field in cancer in the past few years has been the investigation by Gross, who found that cell-free filtrates of tissues of the strain of mouse (*AKR*) liable to leukæmia, when injected into day-old C_3H mice, induced leukæmia and salivary gland cancer at a later stage. Salaman has now found that cell-free filtrates ('Gradocol') of leukæmic tissue from spontaneous leukæmia in *AKR* mice injected into 17 hr.-old C_3H mice induced 40 tumours in 15 out of 23 surviving mice; 22 were tumours of the salivary gland. The remainder were subcutaneous tumours of the thoracic and abdominal wall and were epithelial in type and closely imitated mammary cancer; a few were sarcomas.

Co-carcinogenesis has been the subject of experiments by Roe; he finds that the bladder as well as the skin of the mouse can be used as tissue for tests. Pellets of paraffin wax, alone or containing croton oil, were implanted in the bladder by the Bonser technique, and urethane was given by stomach tube in some of the experiments. When the bladder wall was examined (*post mortem*) after the tests had been carried on for 40 weeks, carcinomata, some of which were invasive, were found in a proportion of the mice. The yield of tumours, while appreciable, was insufficient for a precise assay; but it was obvious that both urethane and croton oil, alone or in co-carcinogenic combination, can induce papilloma and carcinoma of the mouse bladder epithelium.

As in previous Reports, a great deal of attention is being given at a number of centres to the study of deoxyribonucleic acid in normal and malignant tissue; one of the most interesting advances is described in the experimental work of Harris and his colleagues at Oxford. Along with other workers he has criticized the assumption made in the important researches of Schoenheimer that the components of all the tissues are in dynamic equilibrium; he points out that, "experiments on animals do not distinguish between intracellular turnover and turnover due to simultaneous multiplication and destruction of cells or to secretion of products by cells". Using the macrophage as an example of a non-multiplying cell and (8-^{14}C) adenine as tracer, he has shown that deoxyribonucleic acid is not synthesized in the cell, and no deoxyribonucleic acid adenine or thymidine was involved in turnover; but the ribonucleic acid was found to have a half-life of 2 hr. when it incorporated exogenous labelled adenine. Using tritium-labelled precursors, no transfer of ribonucleic acid from nucleus to cytoplasm could be detected and the half-life of nuclear ribonucleic acid was found to be 2 hr. both in macrophages and in connective tissue cells.

Table 1. PERCENTAGE CONVERSION OF ADDED ^{14}C-LABELLED GLUCOSE AND SUGAR ALCOHOLS TO CARBON-14 DIOXIDE

500 mgm. slices or cells incubated in Krebs–Ringer bicarbonate solution containing 20 mgm. labelled substrate (0·2 μc. ^{14}C) for 3 hr. at 37° C. Results are given ± S.E.M.

Tissue	D-Glucose	D-Sorbitol	D-Arabitol	D-Xylitol
Spleen	5·0±0·6	1·1±0·2	0·17±0·03	1·8
Thymus	3·5	—	0·1	—

DAB hepatoma	4·1±0·7	1·4±0·5	0·15±0·03	2·1±0·1
β-Propiolactone tumour	7·0	0·62	0·12	—
Ascites tumour cells	4·7±0·4	0·87±0·08	0·10	—

It is now more than thirty years since the carbohydrate metabolism of tumours was used by Warburg as a basis for his hypothesis of the characteristics of malignancy; this theme is still a subject for experimentation and controversy. Glock and McLean have adapted the radiocarbon-labelling technique to the study of the glucose metabolism of normal tissues and tumours. Their results are shown in Table 1, and suggest that when rat liver becomes converted to hepatoma by dimethylaminoazobenzene (DAB), some of the characteristics of the carbohydrate metabolism are lost; but in this respect the resulting malignant tissue can scarcely be distinguished from some other normal tissues. Results for the metabolic capacities of the normal tissues (if obtainable), which were the origins of the β-propiolactone-induced tumour and the ascites tumour, would constitute the essential material for adequate comparison.

Physicists become more and more concerned with less in the field of radiation, and a very large number of the reports from physicists working in this field of cancer research are concerned with identifying and measuring amounts of radiation that are considerably less than those met with in the more usual radiological or radiotherapeutic fields. Very keen interest is being taken in environmental radioactivity, and reports of the measurement of the activity from building materials have been supplemented by those dealing with ingested naturally occurring radioactivity. It is reported that Brazil nuts contain more than 20,000 times the activity found in other common foodstuffs. New and more sensitive methods of detection of β- and γ-radiations have been produced, so that it is now possible to detect as little as 20 μμc. cæsium-137 in a single human milk sample. These advances are of great importance in the study of the radiation-levels received by the population in various areas depending on their dietary habits, on the geological nature of the area in which they live and on the type of materials used in the buildings in which they live and work.

The results of experiments carried out to discover the effects of prolonged irradiation at low levels of dosage on mice indicate a premature ageing under such experimental conditions, and this finding confirms the need for such research into the nature of the irreducible natural radioactive background which is present before the addition of increased man-made radioactive contamination into the daily lives of a large proportion of the population.

The radiation dosimetry in bone from bone-seeking radioactive isotopes is being studied in several centres, and practical confirmation is being obtained of the theoretical calculations which have been reported previously. The correlation of the dose received by the sternal marrow during irradiation treatment with the hæmatological findings in such sternal marrow samples is also being studied. Experiments are also reported which are designed to provide further confirmation of Dr. R. H. Mole's observations that the important factor in the production of radiation leukæmia is the dosage-rate rather than the total dose received.

Confirmation of the advantages of radiotherapy with megavoltage radiation is reported from centres all over the world, and the installation and calibration of such equipment necessitate a considerable amount of time being spent on the basic physical measurements which are necessary before the equipment can be put into routine use.

Instruments for the continuous integration and recording of solar erythomal ultra-violet radiation have been designed in Queensland, Australia. This equipment will be used in conjunction with a survey which is now being made of various aspects of the occurrence of skin cancer in an attempt to assess the chief factors causing skin cancer.

Work is also continuing in several centres on the response of tumours to irradiation in atmospheres of various concentrations of oxygen. The radiosensitivity of normal and of malignant cells alike has been found to be under the control of the concentration of dissolved oxygen in the immediate environment of the cell. The administration of oxygen under pressure aims at raising tissue oxygen tension and hence tumour sensitivity by supercharging the plasma with dissolved oxygen.

An interesting application of the Sandberg–Moore technique for detecting tumour cells in venous blood is reported from the Middlesex Hospital, London. In addition to samples of peripheral venous blood and of blood from veins draining the tumour, samples of hepatic vein blood were taken by trans-cardiac catheterization in order to assess the ability of the liver to clear tumour cells from the blood passing through it. The nine cases of gastro-intestinal cancer in which samples were taken from both portal vein and hepatic vein are of particular interest. Tumour cells (certain or suspicious) were seen in eight cases in the portal vein and in only two in the hepatic. Though the numbers are small, they strongly suggest a very substantial filtration effect by the liver. Curiously enough, even in gastro-intestinal tumour, the peripheral blood appears to be more often positive than the hepatic vein, and though the numbers are again too small to be reliable, this would if confirmed suggest in the first place a substantial by-pass of the liver (perhaps by tumour cells passing up the thoracic duct) and in the second place that the lung is a very much poorer filter than the liver.

A group at Mount Vernon Hospital presents interesting findings on the deoxyribonucleic acid content of the nuclei of tumours, using micro-spectrophotometry of Feulgen-stained preparations. Of 100 carcinomata of the cervix uteri, 40 had modal values at or near the normal diploid value, and 32 near the tetraploid value. No clear relation between ploidy and degree of differentiation was noted, though adenocarcinomata had high figures and both of two tumours of mixed histology had very variable nuclear deoxyribonucleic acid with no defined mode. Limited observations on recurrent tumours suggest that high-count tumours are more resistant to radiation and that recurrences have a higher count than the original tumour. In tumours from women, the presence of the sex chromatin (the small body which represents the heterochromatin of the *XX* chromosome pair in man and some other animals) can be roughly correlated with the degree of ploidy, being usually present in diploid and often double in tetraploid tumours.

OBITUARY

Mr. E. W. B. Gill, O.B.E.

Ernest Walter Brudenell Gill died on December 20 at Watlington, Oxon, after a long illness, at the age of seventy-six. Born in London, the son of a canon, educated at Bristol Grammar School and Christ Church, Oxford, where he was an Open College Exhibitioner in mathematics and later a Scholar, he took a first-class in physics in 1905, a B.Sc. degree in 1909, became University demonstrator in the Electrical Laboratory under Townsend, and a Fellow (1910) and later the domestic bursar of Merton College, Oxford.

During the First World War he served in the Royal Garrison Artillery and the Royal Engineers Wireless Intelligence, which took him to the Middle East. Afterwards he wrote a witty little book, "War, Wireless and Wangles". During the Second World War he again was in Intelligence and operational research. He was a co-inventor of 'window', metal foils dropped from planes so that our aircraft could not be located by enemy radar; he also worked on devices for guiding tanks. After the War he and an American representative interviewed the German scientists. He was surprised to find how little they had contributed to the war effort, some pretending that this was to save the world from destruction. A humorous account of his experiences, intended as a book, remains in the manuscript stage.

Gill's numerous scientific contributions cover a wide range of physical problems. With Pidduck he measured the ionization coefficient in helium. He discovered the effect of the electric field on the saturation current of tungsten emitters in valves and developed an ingenious method of determining the high-frequency conductivity and dielectric constant of the soil by measuring the ratio of the vertical and horizontal components of electric field and the phase angle between them. He investigated extensively electrodeless discharges in high-frequency electric fields, and observed that at very low gas pressure the starting potential becomes very small when a magnetic field applied perpendicular to it is of such value that electrons move through their orbit in a time equal to their periodic time (1937), an effect recently spectacularly demonstrated by Cutolo in Naples, who started a discharge a long distance from the transmitter of an electromagnetic beam. With me he found that in zero magnetic field the initial multiplication of charges at low pressure is due to secondary electrons released from the walls of the glass-vessel. He contributed greatly to our knowledge of static electrification, showed that frictional electricity is caused by contact potentials and found that by freezing-in charges in ice surrounded by water, potential differences of several 100 volts appear across the ice. Later he turned his fertile mind to the elucidation of the mechanism of the rise of sap in trees.

Gill was an outstanding Englishman, a gay character, modest, with an inborn sense of humour and a fund of excellent stories. He had the original mind of a young man coupled with the neat approach of a professional soldier. Debunking ("rebuking sin") was his hobby. Because of his independent judgment, his unfailing logic and his devastating remarks (often noted by the Press), he stepped quite often on people's toes. He never received the recognition he deserved either as a scientist or for his work in the administration of the University or as an Alderman of the City. He was a trusted friend and a devoted husband, who is survived by his wife, three sons and one daughter.

A. von Engel

NEWS and VIEWS

National Agricultural Advisory Service: W. Morley Davies

Mr. W. Morley Davies has retired from his post of senior advisory officer in the National Agricultural Advisory Service. He attended the University of Birmingham, taking a degree in chemistry and botany. During the First World War he was engaged on the manufacture of explosives in British Dyestuffs, Ltd., Huddersfield. Afterwards, he went to Gonville and Caius College, Cambridge, as a research student and worked in the School of Agriculture under Prof. T. B. Wood and Arthur Amos, taking a research B.A. in 1922. At the same time, he also obtained the agricultural diploma. In September 1922 he was appointed head of the Department of Chemistry at the Harper Adams Agricultural College, and later, in 1924, was also appointed as advisory agricultural chemist to the West Midland Province. During that period, mainly in collaboration with the late Prof. G. W. Robinson, Prof. T. Wallace, Sir William Ogg and others, many of the methods now in use in the Soil Survey were developed. In 1946 he was appointed the first director of the East Midland Province in the newly constituted National Agricultural Advisory Service. He was appointed senior education and advisory officer in charge of all the science sections of the Service and stationed at headquarters in London in 1949. As chairman of the Land Restoration Committee and also of the Technical Advisory Conference on the Restoration of Opencast Coal Land, he piloted much work on the technical problems of restoring land to agriculture after it had been subjected to mineral working. He was also a member of the Ironstone Advisory Committee appointed by the Ministry of Housing and Local Government. During the period at headquarters he was secretary of the Agricultural Improvement Council (England and Wales) and assessor for the Ministry of Agriculture on several of the committees of the Agricultural Research Council as well as on the Geological Survey Board.

Dr. N. H. Pizer

Dr. N. H. Pizer, who will succeed Mr. Morley Davies, has been regional soil chemist in the Eastern Region of Great Britain since 1946 and has been interested in soil conditions affecting root development and nutrition of crops, particularly those related to soil conformation and structure. Physical defects such as compacted or structureless layers have been found to occur in many soils and to impede drainage, root development and root activity. Some are due to treatment of the soil and others are natural, and their effects on crops vary with season. Methods of dealing with these defects have been worked out with the farmers concerned. Some defects have required drainage operations or cultivations to a suitable depth when the soil was dry, and others a combination of the two. Dr. Pizer has also worked on the amount and distribution of organic matter in soils under different systems of husbandry and the effects which very low levels of organic matter may have on the physical condition of soils and their ease of working. Another of his interests has been the occurrence of trace-element deficiencies in crops and the development of methods of recognition and treatment. As a result of this work, copper deficiency was found to occur in cereals growing on many fen peat soils and on very light sandy soils previously reclaimed from heath. Yields of cereals were increased from a few cwt. an acre to more than 30 cwt. by the application of ¼–1 lb. of copper per acre as a foliar spray.

After the sea floods of 1953 which affected most of the coast-line of eastern England and extended inland up the river valleys, considerable work was done in the field and laboratory on methods of restoration of soils. Much variation was found between soils in the effects of salt on their physical condition, some being extensively damaged and others not at all, and these variations had an important influence on the treatment that was recommended to restore the land to its former condition. More recently, the problem of magnesium deficiency in fruit crops, glasshouse crops and arable crops on light land has been studied and practical methods of treatment developed.

Paul Instrument Fund: Awards

Awards of grants by the Paul Instrument Fund Committee have been made as follows: £500, in supplement of a previous grant, to Dr. B. V. Bowden, principal of the Manchester College of Science and Technology, for the development of narrow pass-band dye filters; £545, in supplement of a previous grant, to Dr. R. Feinberg, of the Department of Electrical Engineering, Manchester College of Science and Technology, for the construction of an instrument for measuring the intensity of soft X-radiation generated in experimental high-voltage valves; £3,000 to Prof.

D. Gabor, professor of applied electron physics in the Imperial College of Science and Technology, London, and Dr. D. Jones, of the Department of Electrical Engineering in the Imperial College, for the development of an electron interference microscope; £8,100 to Dr. H. H. Hopkins, reader in optics, Department of Physics, Imperial College of Science and Technology, London, for the development of methods of drawing and coating fine glass fibres, and their alignment in ordered bundles for the transmission of optical images; £3,000, in supplement of a previous grant, to Prof. R. O. Redman, professor of astrophysics in the University of Cambridge, for the construction and testing of a thin astronomical mirror of plate glass and of a new type of support system; £6,000, in supplement of a previous grant, to Dr. C. N. Smyth, of University College Hospital Medical School, London, and Mr. F. Y. Poynton, of Northampton College of Advanced Technology, London, for the construction of an ultrasonic microscope.

The Paul Instrument Fund Committee, composed of representatives of the Royal Society, the Physical Society, the Institute of Physics and the Institution of Electrical Engineers, was set up in 1945 "to receive applications from British subjects who are research workers in Great Britain for grants for the design, construction and maintenance of novel, unusual or much improved types of physical instruments and apparatus for investigations in pure or applied physical science".

Commonwealth Scholarship Commission in the United Kingdom

The following have been appointed members of the Commonwealth Scholarship Commission in the United Kingdom by the Secretary of State for Commonwealth Relations, Lord Home, and the Secretary of State for the Colonies, Mr. Ian Macleod: The Earl of Scarbrough, the Lord Chamberlain (*chairman*); Dr. R. S. Aitken, vice-chancellor of the University of Birmingham; Sir David Anderson, recently director of the Royal Technical College, Glasgow; Sir Eric Ashby, master of Clare College, Cambridge; Sir Eric Coates, Finance Minister of the Governor General of India's Executive Council, 1946; Lord Geddes of Epsom, member of the London Transport Executive; Sir Hector Hetherington, principal and vice-chancellor of the University of Glasgow; Sir Francis Hill, chairman, General Purposes Committee of the Association of Municipal Corporations; Sir Cyril Hinshelwood, Dr. Lee's professor of chemistry in the University of Oxford, and president of the Royal Society; Sir Douglas Logan, principal of the University of London; Lady Ogilvie, principal of St. Anne's College, Oxford; Sir Julian Pode, managing director of the Steel Company of Wales, and chairman of the Managing Committee of the United Kingdom for the Athlone Fellowships scheme; Sir Paul Sinker, director general of the British Council, and First Civil Service Commissioner, 1951–54; Dr. R. W. West, principal of Battersea College of Technology. The Commission has been set up under the Commonwealth Scholarships Act recently passed by Parliament to administer the Commonwealth Scholarship and Fellowship Plan in Great Britain.

A Hundred Years of Optics

In 1860 John Henry Dallmeyer took out a patent and issued his first Triple Achromatic lens, marking the foundation to the House of Dallmeyer. J. H. Dallmeyer was born in Westphalia in 1830 and went to Great Britain in 1851. He first set up a business designing and manufacturing lenses and optical instruments at 19 Bloomsbury Street, London. In 1861 he was elected a Fellow of the Royal Astronomical Society, and four years later invented the Dallmeyer Rectilinear lens. Improvements in optical technology brought about the series of *f*/3, *f*/4 and *f*/6 Patent Portrait lenses. The management of the business gradually devolved upon Thomas Rudolph Dallmeyer, who, like his father, possessed a wealth of knowledge in optics. In 1891 the first practically useful telephoto lens was designed and issued by him, only to be followed by the Adon telephoto lens in 1892. One of the earliest treatises on the use of telephoto lenses was to his credit, and "Telephotography" was published in 1899. T. R. Dallmeyer died in 1906, and it was only due to the fact that a private limited company had been formed in 1892 that the business remained established. Later developments included the pioneering of the first fixed-separation telephoto lens, the inventions of the Dallon Fixed-separation Telephoto lens and the Pentac anastigmat lens. It was the Pentac lens that created new standards in large-aperture anastigmal lenses, and which was used during the Second World War for aerial reconnaissance both by day and night. It is with much credit to its pioneers that the House of Dallmeyer celebrates its centenary.

Public Health Laboratory Service in Britain

The Public Health Laboratory Service Bill, which received its second reading in the House of Lords on February 4, transfers the administration of the Public Health Laboratory Service in Britain from the Medical Research Council to a new Public Health Laboratory Service Board appointed by the Minister of Health and subject to his directions. The Board will consist of a chairman and nine other members, one of whom must be medically qualified; two members will be appointed after consultation with the Medical Research Council, two must have had experience as bacteriologists, two will be medical officers of health of local authorities, and two with administrative experience. Clauses in the Bill transfer the staff of the Public Health Laboratory Service from the Medical Research Council to the new Board, and property held for the Public Health Laboratory Service is transferred to the Minister of Health. In introducing the Bill, the Minister for Science, Lord Hailsham, explained that the Service had its origin in an emergency service created shortly before the Second World War at the request of the Committee of Imperial Defence, in order to provide a defence against possible enemy use of bacteriological warfare and against any major outbreaks of epidemic diseases arising from war-time conditions. In the event it was never used to deal with any such major emergency, but it proved a very valuable aid to the medical officers of health in their ordinary work, in view of the inadequacy of the arrangements for bacteriological work for public health purposes. Unlike the Hospital Laboratory Services, it was organized on a national and not on a regional or hospital basis, and consists at present of the Central Public Health Laboratory, eight regional and 51 area laboratories, with several special reference libraries; of the staff of about 1,068, 126 are medically qualified. £1,212,000 was provided for the cost of the Service in the Civil Estimates for 1959–60 and another £50,000 for capital expenditure on buildings. Replying to Lord Taylor, who paid tribute to the immense amount of research carried out by the Service (estimated at about one-quarter of its work), Lord Hailsham readily gave the assurance requested that its research activities would not be curtailed.

British Overseas Information Services

In the House of Commons on February 1, the Chancellor of the Duchy of Lancaster, Dr. C. Hill, gave the estimated cost of the overseas information services during 1959–60 as £16,966,140, of which 30·3 per cent was attributable to the British Council, 39 per cent to the British Broadcasting Corporation's External Services, 18·3 per cent to the Foreign Office, 8·4 per cent to the Commonwealth Relations Office, and 3·7 per cent to the Colonial Office. There were 117 United Kingdom information posts overseas, of which nine were staffed by one United Kingdom-based officer only, and three by one locally-recruited officer only.

Research and Industry in Great Britain

In reply to a question in the House of Commons on February 4, the Minister of Education, Sir David Eccles, as representing the Minister for Science, said that the research needs of the printing machinery, textile machinery and shipbuilding industries were among those being considered for special study by the Department of Scientific and Industrial Research. Since the full co-operation of the firms concerned was essential, an inquiry on a confidential basis was proposed. The report would afterwards be discussed by the industry and steps taken to remedy any defects.

Courses on Nuclear Energy for Engineers and Technical Industrialists

Two international courses on nuclear energy, designed for senior engineers and technical industrialists, are being arranged this summer by the European Nuclear Energy Agency of the Organization for European Economic Co-operation. One course will be at the Centre d'Etudes Nucléaires at Saclay (France) and the other at the Atomic Energy Research Establishment, Harwell. Each will be open to some fifty participants from countries belonging to the Organization, and will cover the technical, economic and industrial aspects of nuclear energy. The course at Saclay (in French) will be held during June 27–July 8; the Harwell course (in English) during July 4–15. The programme in each case will comprise lectures, practical work and visits to installations, and will be presented throughout from the point of view of the engineer and the industrialist. Further information can be obtained from O.E.E.C. European Nuclear Energy Agency, 38 Boulevard Suchet, Paris 16.

Courses in Advanced Technology

The wide range of part-time courses dealing with advanced aspects of technology provided by technical institutions in the London area is described in a bulletin prepared by the London and Home Counties Regional Advisory Council for Technological Education. At Balham and Tooting College of Commerce experts from foreign embassies were invited to discuss the problems of British export policy. A course on energy approximations in structural design was arranged at Battersea College of Technology, while at the Borough Polytechnic bakery sales manageresses were invited to learn how better to sell bakery products. Joinery estimating was available for joinery managers and shop foremen at the Brixton School of Building, and new developments in gas chromatography were available at the Brunel College of Technology. At the City of London College senior executives of tanker operating firms were invited to a series of lectures on the economics of tanker shipping operations. Further details of the bulletin can be obtained from the Secretary, Regional Advisory Council, Tavistock House South, Tavistock Square, London, W.C.1.

The Leopoldina German Academy of Sciences: Elections

The Deutsche Akademie der Naturforscher Leopoldina, Halle, recently elected the following new members, in the sections indicated: *Zoology*, Prof G. P. Baerends (Haren (Gron.) Holland), Prof. Willi Hennig (Berlin), Prof. Werner Jacobs (Munich), Dr. Martin Lindauer (Munich), Prof. Hans J. Müller (Quedlinburg), Dr. Johann Schwartzkopff (Munich), Prof. Niko Tinbergen (Oxford); *Physical Chemistry*, Prof. Gustav Kortüm (Tubingen), Prof. Werner O. Köster (Stuttgart); *Internal Medicine*, Prof. Ferdinand Hoff (Frankfurt/M.), Prof. Hugo Wilhelm Knipping (Cologne), Prof. Ernst von Lauda (Vienna), Prof. Paul Martini (Bonn), Prof. Helmuth Reinwein (Kiel), Prof. Rudolf Schoen (Göttingen).

Clough Memorial (Geological) Research Fund

The Clough Memorial Research Fund of the Edinburgh Geological Society is available for geological research in Scotland and the North of England (Northumberland, Durham, Cumberland, Westmorland and Yorkshire). Grants for the period April 1, 1960–March 31, 1961, will be made shortly, and applications, stating the nature of the proposed research, should be sent before March 31 to the Secretary, Clough Memorial Research Fund Committee, Edinburgh Geological Society, Synod Hall, Castle Terrace, Edinburgh 1.

University News:

London

Dr. H. O. Schild, reader in pharmacology at University College, has been appointed to the University chair of pharmacology tenable at that College, as from October 1, 1961; and Dr. W. F. Widdas, reader in physiology at King's College, has been appointed to the University chair of physiology tenable at Bedford College, as from October 1, 1960. The following appointments are also announced: Dr. H. Lehmann, senior lecturer in chemical pathology at St. Bartholomew's Hospital Medical College, to the University readership in chemical pathology tenable at that College; and the title of reader in chemical pathology in the University of London on Dr. G. R. Webster in respect of his post at Guy's Hospital Medical School.

Oxford

It is announced that the Forestry Commission is to make a grant not exceeding £4,000 for two years beginning April 1, 1960, for the continuation of an investigation into the costs of private forestry and economic information concerning private forestry estates in England and Wales, being carried out in the Department of Forestry under the direction of J. J. MacGregor.

The Night Sky in March

Full moon occurs on Mar. 13d. 08h. 26m. U.T., and new moon on Mar. 27d. 07h. 38m. The following conjunctions with the Moon take place: Mar. 5d. 00h., Aldebaran 0·4° S.; Mar. 20d. 11h., Jupiter 5° S.; Mar. 21d. 14h., Saturn 4° S.; Mar. 24d. 04h., Mars 4° S.; Mar. 25d. 12h., Mercury 0·7° S.; Mar. 25d 12h., Venus 2° S. In addition to these conjunctions with the Moon, Mercury is in conjunction with Venus on Mar. 25d. 09h., Mercury being 1·9° N. There will be a total eclipse of the Moon on March 13 and a partial eclipse of the Sun on March 27, both eclipses being invisible at Greenwich. Mercury can be seen during the first few days of the month as an evening star, but conditions rapidly become unfavourable, and after March 5 Mercury will be too close to the Sun for easy observation. There is an occultation of Mercury by the Moon on March 25, visible from Greenwich and lasting from 11h. 51·1m. to 13h. 03·6m. Venus and Mars are too close to the Sun for easy observation. Jupiter is a morning star, rising at 3h. 30m, 2h. 40m. and 1h. 45m. on March 1, 15 and 31, respectively. It may be seen in the south-east before sunrise; it is in Sagittarius. Its stellar magnitude is $-1 \cdot 7$ and its distance from the Earth in the middle of the month is 490 million miles. Saturn is a morning star, rising at 4h. 30m., 3h. 40m. and 2h. 40m. on March 1, 15 and 31, respectively. It is visible in the south-east before sunrise, and, like Jupiter, is in Sagittarius. Its stellar magnitude is $+0 \cdot 8$ and its distance from the Earth on March 15 is 960 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Mar. 4d. 20h. 40·6m., θ^1 Tau. (*D*); Mar. 4d. 20h. 44·2m., 75 Tau. (*D*); Mar. 4d. 21h. 40·3m., 264 B. Tau. (*D*); Mar. 5d. 00h. 00·2m., 111 Tau. (*D*); Mar. 11d. 3h. 18·0m., o Leo. (*D*); *D* refers to disappearance. The vernal equinox occurs on March 20d. 15h.

Announcements

A decision by the U.S.S.R. to join the International Federation of Computer Societies brings the number of nations which have ratified the statutes of this new international organization up to twelve. The Academy of Sciences of the U.S.S.R. will be represented in the Federation by its Computing Centre.

An international symposium on Growth: Molecule, Cell and Organism will be held at Purdue University, Lafayette, Indiana, during June 16–18. Further information can be obtained from Prof. M. X. Zarrow, Department of Biological Sciences, Purdue University.

The annual International Starch Conference is to be held at the West German Starch Research Station, Detmold, during April 20–22. Further information can be obtained from W. Kempf, Cereal Research Station, P.O. Box 23, Detmold, West Germany.

A conference on the Computing Laboratory in the Technical College is to be held during May 27–28 at the Hatfield Technical College, which is sponsoring it. Further details can be obtained from W. A. J. Chapman, Department of Mathematics, Hatfield Technical College, Hertfordshire.

The Chemical Society is organizing a symposium on Physical, Chemical and Biological Methods of Study in High Molecular Weight Carbohydrates, to be held in Edinburgh during July 12–14, 1960. Further information can be obtained from the General Secretary, Chemical Society, Burlington House, London, W.1.

The fifth International Congress on Nutrition will be held in Washington, D.C., during September 1–7, under the auspices of the International Union of Nutritional Sciences. Dr. C. Glen King (The Nutrition Foundation, New York City) will preside over the Congress. Further information can be obtained from Dr. Milton O. Lee, 9650 Wisconsin Avenue, Washington 14, D.C.

The general programme of the Madrid Sectional Meeting of the World Power Conference during June 5–9 has now been published. British subjects wishing to obtain further information should write to the Secretary, British National Committee, 201–2 Grand Buildings, Trafalgar Square, London, W.C.2, from whom copies of the programme can also be obtained.

A conference on Solid State Microwave Amplifiers is being organized by the Electronics Group of the Institute of Physics, in conjunction with the Radio Spectroscopy Group, at the University of Nottingham during April 6–8. Further details can be obtained from the Secretary, Institute of Physics, 47 Belgrave Square, London, S.W.1.

The International Medical Congress, Ltd., which has a strong affiliation with the National Foundation of New York, is holding its first International Conference on Congenital Malformations in London during July 18–22. Further information can be obtained from the Executive Secretary-Treasurer, First International Medical Conference on Congenital Malformation, 67 New Bond Street, London, W.1.

The Pesticides Group of the Society of Chemical Industry is organizing a symposium on Fungicides in Agriculture and Horticulture in the spring of 1961. It would be appreciated if workers on these subjects who may wish to submit a contribution to this symposium would get in touch with the hon. secretary of the Pesticides Group, Dr. B. J. Heywood, c/o May and Baker, Ltd., Dagenham, Essex, giving a very brief indication of the scope they would wish to cover.

Prof. R. A. McCance and the Department of Experimental Medicine, Cambridge, are arranging a course on the Clinical Aspects of Nutrition, to be given in the Department of Geology, Cambridge, during April 6–9. The course is open to university and hospital medical and scientific staffs and registered medical practitioners. Further information can be obtained from the Secretary, The Medical School, Tennis Court Road, Cambridge.

The second European symposium on Chemical Reaction Engineering is to be held at the Koninklijk Instituut voor de Tropen, Amsterdam, during April 28–30. The symposium is being organized under the auspices of the European Federation for Chemical Engineering by the two Dutch member societies. Further information can be obtained from P. J. Hoftyzer, Central Laboratory, Staatsmijnen in Limburg, Geleen (L), Netherlands.

Erratum. We regret that in the communication entitled "Shape of the Precipitate in Immunoelectrophoresis", by Dr. Jan Hirschfeld, in *Nature* of January 16, p. 164, Fig. 4 has been printed upside down.

THE INTERNATIONAL COMMITTEE ON LABORATORY ANIMALS

By Dr. W. LANE-PETTER

Laboratory Animals Centre, Carshalton, Surrey

IN December 1956, the International Committee on Laboratory Animals was formed, and a report of this event appeared two months later in *Nature* (179, 240; 1957), describing its background, composition and purpose. After three years, it is timely to review its work and achievements.

The Committee is to-day supported, by direct grant and by representation, by the Council for International Organizations of Medical Sciences; the International Unions of Biological and of Physiological Sciences; and by direct assistance other than cash grants by Unesco. It consists of: Prof. J. H. Maisin (Belgium), chairman of the Committee and representative of the Council for International Organizations of Medical Sciences; Prof. W. K. Hirschfeld (Holland), vice-chairman; Prof. G. Montalenti (Italy), representing the International Union of Biological Sciences; Prof. J. A. B. Gray (United Kingdom), representing the International Union of Physiological Sciences; three members co-opted under the by-laws for a two-year term from October 1958: namely, Dr. Dale W. Jenkins (United States), representing the International Committee on Laboratory Animals in the American Continent; Monsieur M. Sabourdy (France), treasurer; and Dr. W. Lane-Petter (United Kingdom), secretary-general; and an observer from Unesco. Meetings of this Committee have been held in December 1957 (Paris), October 1958 (Paris) and April 1959 (London). The next meeting will be held in April 1960 in Rome.

Already in December 1956, Unesco had initiated surveys on the production and utilization of laboratory animals in a number of countries, and further surveys have since been commissioned and carried out, on the advice of the Committee. Some have been published, in consolidated form, by the Committee as mimeographed documents: Vol. 1 including India, Italy, Japan, Switzerland and the United Kingdom: Vol. 2, Denmark, Finland, Iceland, Norway, Sweden, and Turkey (first supplement); Federal Republic of Germany and Austria (second supplement); and Australia (third supplement). A third volume will include Belgium, Netherlands, France, Israel, Poland, Czechoslovakia, and probably a partial survey of the United States.

From these surveys has come a clear picture of the actual production and utilization of laboratory animals in many different countries; of the varying special problems, and of the underlying basic needs, which are everywhere the same; and an indication of the way in which an international organization such as the Committee can make itself most useful.

As a further attempt to clarify the task that the Committee had undertaken, a symposium was held in Paris in October 1958; a report of this is still in preparation, but will appear very shortly. At the symposium three main questions were examined. First, what were the detailed requirements in the main biological disciplines using animals: namely, cancer research, radiobiology, microbiology, physiology, cell and tissue culture, endocrinology, and pharmacology and the pharmaceutical industry. Secondly, to what extent were these needs being met to-day in different countries. Thirdly, what were the future possibilities, with special reference to genetics, the control of latent infections, the introduction of new species into laboratory use, and the problems of large-scale production of familiar species.

Since September 1957, the Committee's *Bulletin* has appeared regularly every six months. It contains current news of the work of the Committee and also an excellent bibliographical service on laboratory animals.

Consultant members of the Committee have paid numerous visits to other countries, mainly in Europe, to advise on the creation or organization of national laboratory animal centres and to co-ordinate the efforts being made in this field. Indeed, this sort of personal contact has been of great value in stimulating interest, in encouraging the setting up of new national organizations and in linking the activities of all these in a common effort. In 1956, three national centres only existed, in the United Kingdom, the United States and France. To-day, centres of one kind or another have been formed in Australia, Belgium, the Federal German Republic, Holland, India, Italy, Japan, and more are likely to form in the near future. Almost all owe something, some even their very existence, to the stimulus provided by the Committee.

In 1959, Unesco placed a contract with Monsieur M. Sabourdy, treasurer of the Committee, for the preparation of a list of definitions of terms used in describing laboratory animals of high quality. Such definitions have been attempted in the past, notably among geneticists, but in the absence of a recognized code widely agreed, they tend to lose their exact meaning and in time to become almost valueless. A code of this kind is a necessary adjunct to drawing up specifications for animals; but it should be emphasized that attempts to draw up specifications should not wait on the completion of a glossary of terms, because the need to define many of the terms will become apparent only when specifications are attempted. There must be mutual reaction between the two endeavours, definition and specification.

Most of the surveys already referred to have directed attention to a universal need, namely, for animal technicians who are systematically trained and qualified for the work of breeding and maintaining the animals of high quality that research workers need in nearly every field. Great Britain has been the pioneer in this field, through the work of the Animal Technicians Association, now about ten years old, but training schemes for animal technicians are in operation in United States, France and Czechoslovakia. In the *Bulletin* of September 1959, detailed notes for training animal technicians were published, based largely on the British experience, but taking into account the different needs and opportunities in other countries. The animal technician is coming to take his place alongside the laboratory technician as an indispensable member of the biological team.

The Committee has already given prominence to the need for national laboratory animal organizations, the four functions of which are : (*a*) to act as an exchange for information about all aspects of animal supply and management ; (*b*) to conduct research into current problems in their production and care ; (*c*) to maintain primary type colonies of animals conforming to exacting specifications, supplying authentic breeding stock for expansion in production units ; (*d*) to train scientists and technicians specializing in this field. For the future, it is planning a second symposium for some time in 1961, on transmissible disease (other than of genetic or nutritional origin) ; the preparation of world lists of primary type colonies of specified strains of animals, and sources of less commonly used species of vertebrates and invertebrates ; as well as continuing the labours already undertaken.

The International Committee on Laboratory Animals started as an informal group, largely self-appointed, to examine a problem that was recognized in many quarters, namely the difficulty in obtaining enough laboratory animals of the right quality for current and future research. It is international in the sense that its membership and interests are already widespread, but it is not yet internationally representative. It is still self-recruiting, and no reason so far exists for it to be otherwise, for its present membership has a strong desire to attract the support of all who share its interests.

The very substantial support so far given by Unesco cannot be expected to continue indefinitely, and the grants given by the international unions are not, and probably never can be, sufficient to cover all its actual and intended activities. If the Committee is to carry on as it has started and to develop usefully, other international governmental agencies should be encouraged to help. Of these, the World Health Organization is an obvious candidate for patronage, because of its involvement in medical research, which is so vitally dependent on good laboratory animals. It is satisfactory to note that the World Health Organization has sent an observer to the last two meetings of the Committee.

It would also be reasonable to expect all countries supporting an active laboratory animals organization to have some representation on the Committee. At present only a few enjoy membership of the Committee, and these would appear to have been somewhat arbitrarily selected. There is little doubt that the lop-sidedness of the Committee, in this respect, will be corrected, and the sooner the better.

There is not only a need, but also great scope for international collaboration in defining and producing good laboratory animals. Without such collaboration there is a danger, already unhappily apparent in many parts of the world, of duplicated effort in solving the major problems in this field ; of parallel but isolated developments in the use of animals which appear different but are similar, or appear similar but are differently or misleadingly designated ; and of research effort being vitiated by the use of inadequate animal material. This fragmentation of endeavour has to be corrected before it goes too far. By the end of the decade we have just entered, we shall probably consider, in retrospect, our current ideas of quality in laboratory animals with astonishment bordering on incredulity that they served our purposes even as well as they do. If this is so, the International Committee on Laboratory Animals will have played an important part in our animal house revolution.

TRAINING SKILLED WORKERS

ALTHOUGH much is made of the skill of British craftsmen and operators, investigations over the past decade have shown how little is known about the components of skill. The result has been that much of the training provided for manual workers is conducted in a hit-or-miss fashion because those concerned with the training are not at all clear about the nature of the skill they are trying to impart and, consequently, even less clear about the teaching of it. One whose researches have been almost entirely concerned with the teaching of skills to unskilled and semi-skilled operatives in a variety of industries is W. D. Seymour, and, in a broadsheet published by the Institute of Personnel Management, he presents some of the experience he has gained in training unskilled and semi-skilled operatives in manufacturing industry. This broadsheet should be warmly welcomed by all concerned with the training of operatives as the clearest and most concise statement which has yet appeared.

The types of work customarily undertaken by unskilled and semi-skilled workers in manufacturing industry can be grouped into the following categories :

Handwork, that is, work which is done exclusively with the operators' bare hands, without the intervention of any tools or machinery. This group of operations still employs a large number of operators and includes wrapping and packing operations, some assembly work, pottery decoration and other examples of very fine work. Some types of inspection work also fall into this category.

Handwork with Tools. This category includes all types of manual work in which hand tools are used, but which do not involve the use of mechanical power. In spite of the increasing mechanization of modern industry, very large numbers of workers are still engaged in these operations with hand tools, which may be of a general nature, for example, screwdrivers and pliers, or may be specially designed for the purpose, for example, the wig-maker's hook. Examples of this type of work are provided by most types of assembly work, pottery figure making, automatic telephone wiring, coil fitting on electric motors, etc.

Single Purpose Machine Work. This category covers all operations where a mechanically or electrically driven machine is used for a single specific purpose. The increasing use of special-purpose machines tends to augment the number of workers employed in this category, though the numbers employed on any one type of machine may be small. Examples are provided by hosiery seaming and linking machines, coil winding machines and cigar making machines.

Multi-Purpose Machine Work. The category includes all types of work done on adaptable power-driven machines, which can be used for a variety of purposes. Typical examples in this category are the capstan lathe and the industrial sewing machine.

Group Machine Work. This category includes those types of work where the operator is responsible for the output from a number or battery of machines, which are automatic or semi-automatic in their operation. Such work is sometimes referred to as machine minding, but frequently involves short complex operations which need to be done efficiently if full production is to be achieved. Automatic capstan-lathe work, weaving and spinning provide examples in this category.

Non-Repetitive Work. Operations in this category are frequently even more important than repetitive work and involve a high degree of responsibility; they include machine setting, loom overlooking or tackling and inspection operations and process work.

Techniques of operator training are now being used in a number of industries in Great Britain, and are also being adopted overseas. Underlying these techniques is the recognition that operator skills in industry are very varied and highly developed, and that training of new workers to acquire such skills must be based on an adequate analysis and understanding of the skills. Furthermore, training must be considered as continuing right up to the point where the new recruit attains the experienced workers' standard of output and quality. Where the skills analysis indicates that a task presents special difficulties of movement or of perception, exercises or devices are designed for preliminary training. Again, after further scrutiny of the analysis, the task is divided into sections suitable for training, special attention being given to those parts which involve perceptual difficulties or decision making. Target standards, equivalent to experienced workers' standards of output and quality, are determined for each section of the work. Trainees, normally in pairs and in a training centre adjacent to, but separate from, the shop, practise the preliminary exercises, then practise the sections of the job and proceed to perform the parts together only when each has been mastered to experienced workers' standard of output and quality. When one cycle of the operation has been performed at experienced workers' standard, trainees attempt 2-, 4- or 8-hr runs, passing to a longer period only when targets have been achieved on the preceding shorter period.

By the use of these techniques in a wide variety of industries, such as mechanical engineering, electrical engineering, screw making, pottery, hosiery, garment and footwear manufacture, knitting, spinning and weaving, and other less common industries, it has been found possible to reduce the time required for new entrants to attain the level of performance of experienced workers to between a half and a third of that previously required. Such a reduction in training time, and the higher productivity achieved, lead to economies which usually far exceed the cost of introducing the training scheme. These techniques are also used for the re-training of existing workers whose productivity is below average. The higher output achieved benefits the operators in higher earnings, and the company in lower overhead costs per unit produced.

In the remainder of the broadsheet Seymour describes the methods he has adopted to analyse the nature of skill and some of the findings. Wider use of these findings could do much to increase the quality of skill among British operatives.

This most useful broadsheet may be obtained from the Institute of Personnel Management, 80 Fetter Lane, London, E.C.4, price 7*s.* 6*d.* T. H. HAWKINS

OBSERVED CHARACTERISTICS OF AN ULTRA-HIGH-FREQUENCY SIGNAL TRAVERSING AN AURORAL DISTURBANCE

By J. C. JAMES, L. E. BIRD, R. P. INGALLS and M. L. STONE
Lincoln Laboratory, Massachusetts Institute of Technology

J. W. B. DAY and G. E. K. LOCKWOOD
Defence Research Telecommunications Establishment, Canada

AND

R. I. PRESNELL
Stanford Research Institute, Menlo Park, California

AN experimental study was made to determine the characteristics of ultra-high-frequency signals propagated through auroral-type disturbances. The experiment was performed by illuminating the Moon from a site in the auroral zone and receiving the reflected signals from the Moon at two receiving sites at mid-latitudes.

The transmitter was located at the Geophysical Institute at College, Alaska. The output power was 10 kW. continuous wave at a frequency of 440 Mc./s. The two receiving sites were located at Shirley Bay, Ontario, near Ottawa, and at the Millstone Hill Field Station at Westford, Massachusetts. Each site used an antenna having two orthogonal polarizations. The signals received were studied carefully to determine whether or not there were any differences when the ionosphere was quiet and when the ionosphere was disturbed by auroral activity.

On at least two occasions a strong auroral disturbance was found in the path to the Moon from the transmitting site at College. On these occasions there were two obvious changes in the characteristics of the received signals: (1) there were rapid fluctuations in the polarization angle; and (2) there was an increase in the rate of fading. However, there was no detectable decrease in average power received during the times of these disturbances.

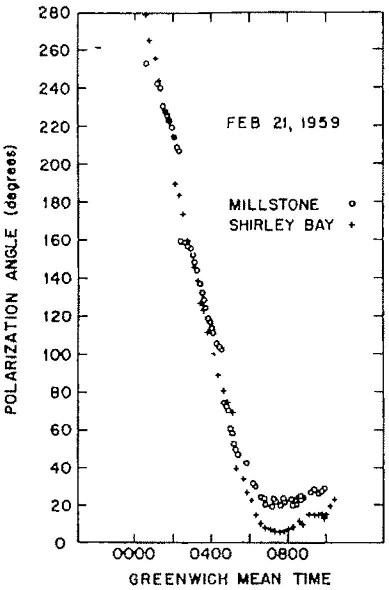

Fig. 1. Variation of the polarization angle of the received signal at the two sites for a day when the ionosphere was quiet

The polarization angle of the signal received was determined by taking the arc tangent of the ratio of voltages in the two orthogonal receiving channels. The quadrant ambiguity resulting from this procedure was resolved by comparing the relative phases of the signals in the two channels before and after a suspected change of quadrant. The polarization angle for a typical lunar day when the ionosphere was quiet is shown in Fig. 1. The polarization angle for this typical run varies slowly with time throughout the day. It was found for these quiet days that the variation of polarization angle could be predicted fairly closely by assuming a certain functional variation of electron density with height, and by adjusting the peak value of this assumed density to match the Central Radio Propagation Laboratory's three-month predictions of 'F-2 Zero MUF'. Account also had to be taken of the relative dipole rotation of the transmitting and receiving antennæ as they tracked the Moon throughout the day with a given polarization.

The measured polarization angles at the two sites for a day when aurora was present are shown in Fig. 2. At about 1400 hr. G.M.T., visual aurora was seen at College in the direction of the Moon. An overcast sky prevented visual observations after about 1500 hr. The rapid fluctuations of polarization angle were apparently caused by the aurora. The computed variation of polarization angle based on a quiet ionosphere is shown by the dashed curve in Fig. 2.

A given change in polarization angle implies a certain change in the number of electrons in the ionosphere, provided certain assumptions are made. One must assume values for the position of the disturbance in electron density and for the magnitude and direction of the magnetic field. On the basis of a stationary magnetic field, the series of fluctuations at 1630 hr. in Fig. 2 represent an incremental change of integrated electron density along a vertical path in the Earth's ionosphere of about 10^{17} electrons per sq. m., assuming that fluctuations in ionization occur below heights of 1,000 km. Very large changes in the direction of the magnetic field are required to explain the observed rapid fluctuations in polarization angle on this basis alone. For example, a change in the direction of the magnetic field of about 20°

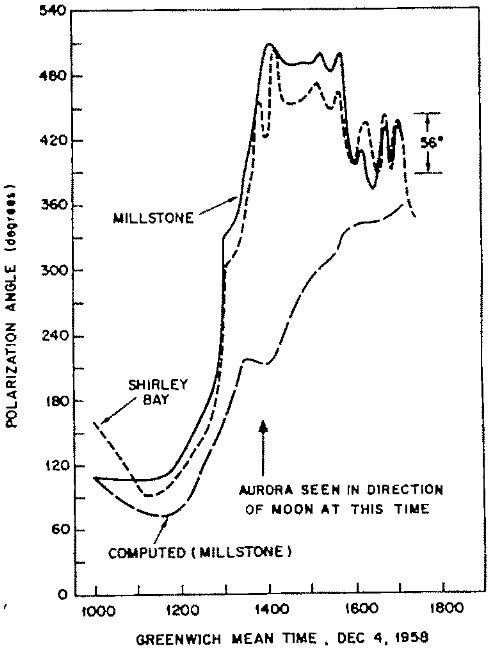

Fig. 2. Variation of the polarization angle of the received signal for a day when the ionosphere was aurorally disturbed. The computed curve is based on a quiet ionosphere

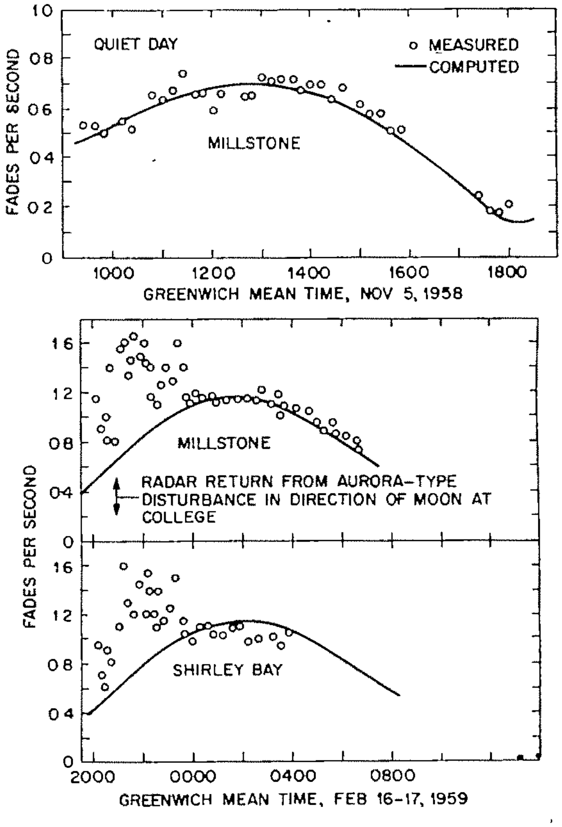

Fig. 3. Comparison of computed and measured rates of fading for a quiet day and an aurorally disturbed day

over a 400-km. height interval in the ionosphere would be required to produce the observed 56° change in polarization angle of Fig. 2 under quiet ionization conditions. This is much larger than any known change in the magnetic field, so most of the rapid fluctuations in polarization angle must be due to rapid changes in ionization density.

During times of an auroral disturbance along the path to the Moon, there was observed an increase in the rate of fading of the received signals. This phenomenon is illustrated in Fig. 3, which shows computed and measured rates of fading for both a quiet day and a disturbed day. During times of a quiet ionosphere, the rate of fading of the received signal was found to be directly proportional to the libration rate of the Moon, an effect that has been reported by others[1]. The predicted rates of fading shown in Fig. 3 were made on the basis of computed rates of libration of the Moon. The top curve illustrates the good agreement obtained between observed and measured rates of fading for normal days. The two lower curves illustrate the increased rates of fading observed during times of auroral disturbances. At approximately 2100 G.M.T. a strong radar return was observed at College from an auroral disturbance in the direction of the Moon. The measured rate of fading at this time was considerably larger than the predicted value made on the basis of Moon libration.

In summary, the significant results reported here are that an auroral disturbance in the path of propagation causes a rapid fluctuation in the polarization angle of the signal received, and an increase in the rate of fading of the signal received, but no measurable absorption of the signal itself. The observed rapid changes in polarization angle are probably due to changes of electron content of the ionosphere of the order of 10^{17} electrons in a vertical column of 1 sq. m. cross-section.

This experiment was a co-operative programme by the following three laboratories: (1) Lincoln Laboratory, a centre for research operated by the Massachusetts Institute of Technology with the joint support of the U.S. Army, Navy and Air Force; (2) Stanford Research Institute, the work of which was sponsored by the Rome Air Development Center of the Air Research and Development Command under Contract *AF* 30 (602)-1762; and (3) the Defence Research Telecommunications Establishment of the Defence Research Board of Canada, the work of which was performed under Project No. *PCC D*48-38-01-11.

We wish to acknowledge the contributions made by our associates at the Lincoln Laboratory, at the Defence Research Telecommunications Establishment, and at the Stanford Research Institute throughout the course of the experiment. We are also grateful for the assistance furnished by personnel of the Geophysical Institute and of the Coast and Geodetic Survey Laboratory at College, Alaska.

OXIDATION OF HYDROXYLAMINE IN CELL-FREE EXTRACTS OF *NITROSOMONAS EUROPAEA*

By DR. D. J. D. NICHOLAS* and DR. O. T. G. JONES*

Long Ashton Research Station, University of Bristol

WE have prepared cell-free extracts of *Nitrosomonas* that will oxidize hydroxylamine to nitrite provided a suitable acceptor such as cytochrome *c* or phenazine methosulphate is added to the extract or to protein fractions prepared from it. Since this is probably the first report of a cell-free system capable of oxidizing hydroxylamine, we give here a brief summary of our main findings.

Cultures of *Nitrosomonas europaea* (kindly supplied by Dr. Jane Meiklejohn, of Rothamsted Experimental Station) were grown in a culture solution based on that used by Meiklejohn[1] and later modified by Walker (private communication): ($(NH_4)_2SO_4$, 0·66 gm.; NaCl, 0·2 gm.; K_2HPO_4, 0·13 gm.; $MgSO_4.7H_2O$, 0·24 gm.; $FeSO_4.7H_2O$, 0·5 gm. adjusted with 5 per cent w/v K_2CO_3 to *p*H 8·5, glass-distilled water to 1 litre). Phenol red was used as an internal indicator and the *p*H of the medium was maintained constant by titrating it continuously with sterile 10 per cent w/v potassium carbonate. Batch cultures of bacteria (300 l.) were grown at the Medical Research Council Antibiotics Research Station, Clevedon, through the courtesy of the director, Mr. B. K. Kelly, and with the help of Dr. R. W. Harrison; their assistance is gratefully acknowledged.

The bacteria suspended in 0·01 *M* phosphate and 0·05 *M* sodium borate buffer (*p*H 8·3) were disintegrated by means of a Mullard ultrasonic probe for 15 min. at 4° C. in a double-walled glass vessel through which iced water was circulated. The homogenate was centrifuged at 20,000*g* for 20 min. at 4° C.; the supernatant solution was used as the source of the crude enzyme and for subsequent fractionation. Enzyme activity was followed by measuring nitrite production from hydroxylamine in the following reaction mixture: 0·1 ml. enzyme, 0·1 μmole hydroxylamine hydrochloride, 0·2 μmole cytochrome *c* (95 per cent pure, Sigma Chemical Company, U.S.A.) or 0·2 μmole phenazine methosulphate contained in 1 ml. of the phosphate–borate buffer (*p*H 8·3). After the stated incubation period (15 or 20 min.), 0·5 ml. of 1 per cent w/v sulphanilamide in *N* hydrochloric acid and 1 ml. of 0·01 per cent w/v N-(1-naphthyl)ethylenediamine dihydrochloride were added and the volume made to 5 ml. with distilled water, and nitrite determined in a 'Spekker' absorptiometer. Enzyme activity was also determined by following oxygen uptake in a Warburg

Per cent inhibition	93	93	85	95	84	90

Silicate and tellurate had no effect.
Reaction mixture: 50 μmoles of the anion, 0·1 μmole cytochrome *c*, 0·1 μmole hydroxylamine hydrochloride in a final volume of 1 ml., phosphate–borate buffer (*p*H 8·8), incubated for 20 min. at 30° C.
Nitrite assayed as in text.

Table 2. FRACTIONATION OF THE ENZYME SYSTEM IN CELL-FREE EXTRACTS OF *Nitrosomonas europaea* THAT OXIDIZES HYDROXYLAMINE TO NITRITE USING PHENAZINE METHOSULPHATE AS THE ACCEPTOR

Fraction	Volume (ml.)	Total units (mμ*M* nitrite/20 min.)	Total protein (mgm.)	Specific activity (mμ*M* nitrite/20 min./mgm. protein)	Purification (fold)	Percentage recovery of enzyme
(1) Crude extract after centrifuging at 20,000*g* for 20 min.	20	6,500	37·4	192		
(2) Fraction collected between 80 and 90 per cent saturation with ammonium sulphate dissolved in 0·01 *M* phosphate and 0 005 *M* borate buffer (*p*H 8·4)	10	2,850	1·1	5,200	27	44
(3) 5 ml. aliquots of (2) put on a *D.E.A.E.*-cellulose column (15 cm. × 1 2 cm.). Column washed in turn with 10-ml. aliquots of the following buffers (*p*H 8·5): 0·05 *M*, 0 1 *M* phosphate-borate; 0·25 *M*, 0 5 *M* phosphate and finally 0·2 *M* pyrophosphate Activity of pyrophosphate eluate	5	510	0 2	8,500	44	8

apparatus in the presence of phenazine methosulphate or cytochrome *c*.

The enzyme activity, which was linear with time when either phenazine methosulphate or cytochrome *c* was used as acceptor, has a *p*H optimum between 7·0 and 8·6. Maximum activity was obtained with 0·2 μmole of either acceptor per 0·1 ml. crude extract containing about 1 mgm. protein per ml. Phenazine methosulphate was the best acceptor, and pyocyanine, methylene blue, benzyl viologen or cytochrome *c* were usually less active, whereas ferricyanide, 2.3.6.-trichloroindophenol dye, coenzymes I and II or glutathione had little effect. Similar results were obtained with whole cells.

When cytochrome *c* was the acceptor, phosphate was required, but at higher concentrations the anion inhibited the oxidation of hydroxylamine as shown in Fig. 1. The phosphate inhibition, which was competitive for cytochrome *c* as shown in Fig. 2, did not occur with phenazine methosulphate. The extent of the inhibition by various anions including pyrophosphate, citrate, tungstate, selenate and arsenate is shown in Table 1. Similar results were

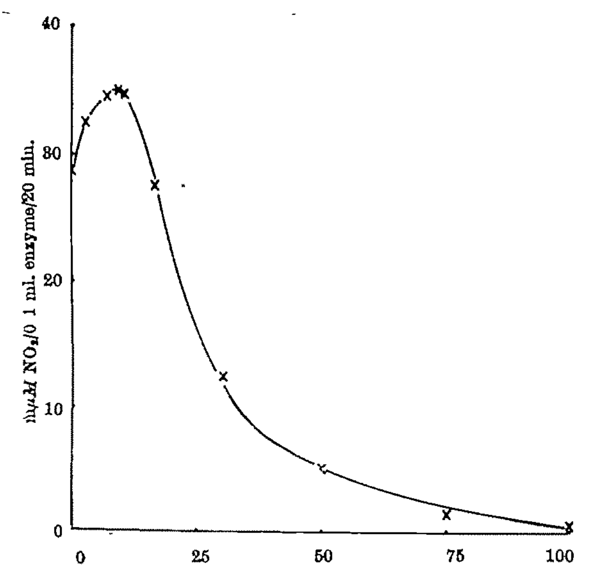

Fig. 1. Effect of phosphate on the oxidation of hydroxylamine to nitrite in a crude extract of *Nitrosomonas europaea*, well dialysed for 12 hr. against 0·01 *M tris* (hydroxymethyl) amino methane buffer, *p*H 8·5
Reaction mixture: 10 μmoles *tris* buffer (*p*H 8 5); 0·2 μmole cytochrome *c*, 0 1 μmole hydroxylamine hydrochloride, 0·1 ml. enzyme contained in 1 ml. incubated for 20 min. at 30° C. Nitrite determined as described in text

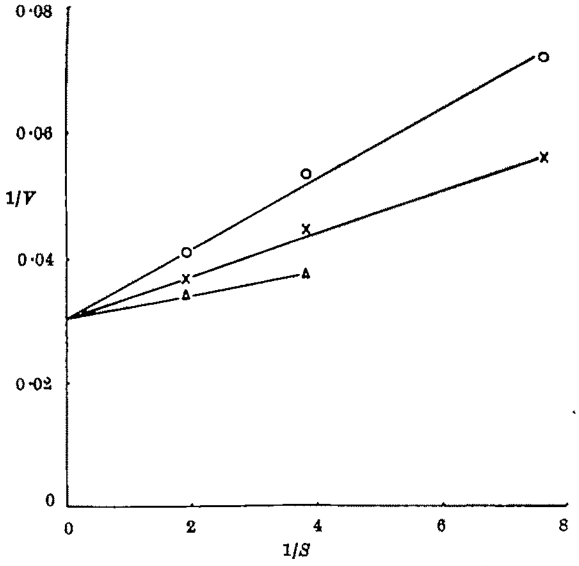

Fig. 2. A Lineweaver–Burk plot for phosphate inhibition of the oxidation of hydroxylamine to nitrite in crude extracts of *Nitrosomonas europaea*, dialysed as described under Fig. 1, using cytochrome *c* as the acceptor
Reaction mixture: 10 μmoles *tris* buffer (*p*H 8·5), 0·1 μmole hydroxylamine hydrochloride, 0·1 ml. enzyme and cytochrome *c* as indicated, contained in 1 ml. incubated for 20 min. at 30° C. Nitrite determined as described in text
1/*S*, reciprocal of cytochrome *c* concentration in mgm. per reaction mixture; 1/*V*, reciprocal of mμ*M* nitrite formed/0 1 ml. enzyme/20 min.

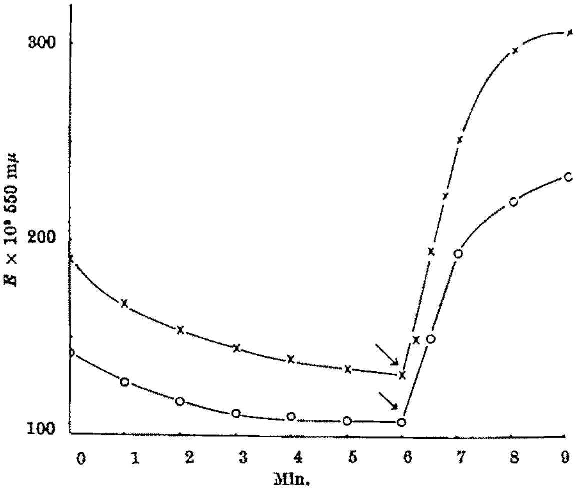

Fig. 3. Effect of hydroxylamine and hydrazine on the enzymic reduction of cytochrome *c* in cell-free extracts of *Nitrosomonas europaea*

+——+, ↓, addition of 0·2 μmole hydroxylamine hydrochloride; ○——○, ↓, addition of 0·2 μmole hydrazine

Reaction mixture in a 1-cm. spectrophotometer cell: 25 μmoles phosphate, 5 μmoles sodium borate buffer (*p*H 8·5), 0·05 μmole cytochrome *c*, in a final volume of 3 ml. and enzymic oxidation of cytochrome *c* allowed to go to completion, then 0·2 μmole of hydroxylamine or hydrazine added

Reaction followed in a Unicam *S.P.*500 spectrophotometer at 550 mμ. Hyponitrite (0·2 μmole), when added instead of hydroxylamine, had no effect. No oxidation or reduction of cytochrome *c* was observed with a boiled enzyme

obtained with whole cells. Hydrazine, a well-known inhibitor of nitrite formation from hydroxylamine in washed cells of *Nitrosomonas*[1], had a similar effect on the cell-free system when cytochrome *c* was the acceptor; but there was no inhibition with phenazine methosulphate. The results in Fig. 3 show that there was an active cytochrome oxidase in the extracts, and the subsequent addition of hydroxylamine resulted in an immediate enzymic reduction of cytochrome *c* with the formation of nitrite. The addition of hydrazine instead of hydroxylamine produced an enzymic reduction of cytochrome *c*, but nitrite was not produced. An increase in hydroxylamine concentration decreased the inhibition of nitrite production by hydrazine. Thus the hydrazine inhibition of nitrite formation in whole cells may be due to a competition with hydroxylamine for a common acceptor such as cytochrome *c* which is indispensable for the oxidation of hydroxylamine. Cyanide inhibited when a range of acceptors was used but carbon monoxide, although depressing cytochrome oxidase activity, did not reduce the oxidation of hydroxylamine to nitrite.

Neither hyponitrite nor ammonia alone was oxidized by these extracts, but the addition of ammonia markedly stimulated the oxidation of hydroxylamine; for example, addition of ammonium sulphate to the reaction mixture at five times the concentration of hydroxylamine stimulated nitrite production by about 60 per cent. Another interesting phenomenon is that the nitrite formed from hydroxylamine in these extracts using cytochrome *c* or phenazine is only 40–73 per cent of the theoretical values expected from the oxygen uptake results obtained in the Warburg. The hydroxylamine was completely oxidized, as confirmed by analysis[3], in agreement with the oxygen uptake. Oxidation with iodine, boiling or acid treatment before the nitrite test did not increase nitrite. When the extracts were aged in the refrigerator for a week or so the nitrite values in the enzyme assays increased, but at best they only approximated to 73 per cent of the theoretical amounts.

A forty-four-fold purification of the enzyme system was achieved by precipitation with ammonium sulphate and further fractionation on diethylaminoethyl-cellulose columns. The pyrophosphate eluate of this column contains the active preparation, using phenazine methosulphate, since pyrophosphate inhibits when cytochrome *c* is the acceptor. The final fraction may contain less protein than that recorded, since pyrophosphate elutes non-protein material from the diethylaminoethyl–cellulose column which reacts with the Folin protein reagents and also absorbs at 260 and 280 mμ.

A more detailed account of this work is in preparation.

RESPONSE OF INBRED AND F_1 HYBRID MICE TO HORMONE

By DR C. K. CHAI

Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine

IN the hands of the biologists the house-mouse is one of the mammals subjected for a long time to continuous mating between close relatives, thereby having attained a high degree of inbreeding and the greatest number of inbred lines with distinct biological characteristics. Because of its biological and genetic uniqueness, and its high rate of reproduction and ease of maintenance, this small-sized mammal has gained recognition as an experimental animal of great value in genetic and medical research and in biological assay. It is on the use of the mouse in bioassays that questions have been raised as to whether inbred mice are superior to random-bred mice and to animals of equal genetic homogeneity but heterozygous, such as F_1 hybrids, produced by crossing two inbred strains.

About two decades ago Emmens[1] found that some F_1 hybrid mice were less variable in response to œstrogen than their inbred parental strains. Later, Mather[2] presented some genetic considerations involved in biological responses. Recently, some data have been presented by McLaren and Michie[3], Claringbold and Biggers[4], and McLaren and Michie[5], and a brief review has been made by Biggers, McLaren and Michie[6] concerning the suitability of using inbred animals as compared with F_1 hybrid animals and random-bred stocks in biological assays. It has been claimed by the latter that inbred animals are not desirable for bioassay on the grounds that they are more variable in responses than either the F_1 hybrid or random-bred animals.

The problem concerning the choice of assay animals requires further consideration. Biological responses involve the reactions in the animal body of one to many systems, all of which are controlled to different extents by the genetic constitution of the individual. The nature of the responses is complicated, and the end-points used are different from one assay to another. However, in determining the precision of an assay, an important parameter which must be considered in quantitative assays—in addition to variance—is sensitivity of response as measured by the slope of the dose–response curve.

This article, which presents some of my experimental results and reviews briefly the results published by others, concerns mainly the sensitivity of response to hormonal substances based on the principles of bioassay and experimental evidence from mice. Some genetic interpretations and general conclusions are made. Although the evidence is drawn from experiments with hormones as assay substances and mice as assay animals, the conclusions reached may be applicable to other drugs and biological preparations and other animal species.

Requirements of an Assay Animal

Biological assays may be defined as determinations of potency or toxicity of a given substance based upon the response of living matter. The nature of the response may be : (1) alteration of internal state —adjustment ; or (2) maintenance of relative constancy of the internal state—regulation. It is very likely that most biological stimuli cause both mechanisms to operate at the same time. For convenience of measurement, biological responses are ordinarily classified into two main categories : (1) qualitative or all-or-none response ; and (2) quantitative. A qualitative response is measured by the percentage of assay subjects with a positive reaction. The most common qualitative data are quantal. An alternative method for quantal data is the use of reaction time, which is relatively seldom used in hormone assays. A quantitative response is very commonly used in hormone assays ; it should give more information per observation than a quantal reaction.

The design of the assay and its computation depend mainly upon the characteristics of the response to be considered. The basic principles for satisfactory assay by Gaddum[7] may be adapted as a guide in the choice of an assay animal. These principles are : (1) a linear relationship should exist between response and dose over the widest possible range of dose ; (2) the standard deviation should be independent of the response ; (3) a minimal value for the ratio s^2/b^2 in quantitative assay and $1/b^2$ in quantal assay, where s^2 is the within-group variance and b is the slope of the dose-response line. (This ratio is called λ^2 by Gaddum.) In addition, good assay animals should give reproducible results, and the precision of an assay should not alter much from test to test or from time to time.

The answer to the question as to whether F_1 hybrids are preferable to inbreds in hormone assay can be derived from calculations based on the formula $\lambda = s/b$ in quantitative assay and $\lambda = 1/b$ in quantal assay. Inbred strains, or F_1 hybrids, which give the smallest λ, offer the most precise assay information or the most information per animal.

In quantitative response, comparison of the assay value between the inbreds and F_1 hybrid animals is therefore based on the ratio of s to b. The ratio may not be minimal when s is minimal, since it depends on the relationship between the two quantities. A slope which is steep enough may compensate for a large variance. Thus, the choice of a mouse strain or F_1 hybrid for bioassay of a given substance is governed by the two parameters in quantitative assay, rather than by either one alone.

In assays involving the quantal response, the precision of the assays depends entirely on b. The value of b, in fact, measures the variation in response of the particular group of animals, for the variances are entirely dependent on b, since $s^2 = 1/b^2$. Unless reliable information is available, the choice of optimum dose-level and adequacy of transformation is frequently a troublesome matter in practice, especially in comparisons of genetically different groups of animals. Inadequate transformations or unsuitable dose-levels easily lead to biased estimates of the true value of b, which in turn results in biased estimations of variance. For this reason the quantitative responses are considered to be more appropriate than the quantal responses in comparing the bioassay value between genetically different groups of animals.

Difference in Sensitivity or Magnitude of Response

Sensitivity is measured by the slope of the dose–response curve. Magnitude of response at a given dose may also be indicative of sensitivity but only when comparing dose–response curves which (1) originate from approximately the same point, and (2) are linear after appropriate transformation. The following examples cover mice of many inbred strains and F_1 hybrids popularly used in bioassays of various hormones. Some of my unpublished results are given first and followed with a tabulation of results published from this and other laboratories.

Response to Androgen. Mice of the *C57BL/6* and *C57BR/cd* inbred strains and their F_1 hybrid BBF_1 were used in this experiment. (The two inbred strains were comparatively closely related and their biological characteristics are rather similar.) The mice were weaned at about four weeks of age, and only those of 9–12 gm. body-weight were used. They were castrated within three days after weaning. Animals were divided into dose groups (eight animals each) in each strain and in the F_1 hybrid mice, and each dose group received a different dose of injection of testosterone in liquid suspension. The injection was begun on the day following castration, one dose a day, and continued for twenty days. The mice were weighed and autopsied on the day following the last injection. The seminal vesicles were removed, blotted thoroughly, and weighed. The means and variances of seminal vesicle weights in each dose group are given in Table 1 and illustrated in Fig. 1. (The methods were similar to a previous experiment using testosterone propionate in different inbred strains of mice—for details see Chai[8].) There

Table 1. MEANS AND VARIANCES OF SEMINAL VESICLE WEIGHTS IN RESPONSE TO TESTOSTERONE IN INBRED AND F_1 HYBRID MICE

Dose (mgm.)	*C57BL/6* mean (mgm.)	s^2	*C57BR/cd* mean	s^2	F_1 (*C57BL/6* × *C57BR/cd*) mean	s^2
0·016	1 9	0 19	2 9	1·33	1·5	0 15
0·032	2·3	1 09	4·4	1 33	3·4	0 58

0·256	26·9	35 63	28·8	19·10	29·8	4·97

Table 2. REGRESSION OF RESPONSE IN PERCENTAGE OF OVARIAN FOLLICLES TRANSFORMED TO PROBITS ON SERIAL DOSES OF HCG IN INBRED AND F_1 HYBRID MICE

Genetic groups	No. mice	Regression equations* ($a + bx$)
DBA/1	80	$4{\cdot}91 + 1{\cdot}25x$
DBA/2	80	$4{\cdot}96 + 0{\cdot}99x$
A	88	$4{\cdot}69 + 0\ 62x$
CAF_1	80	$5{\cdot}19 + 0\ 64x$
BALB/c	70	$5\ 61 + 1{\cdot}27x$

* a, fitted constant; b, slope; x, log dose.

appears to be no difference in the slope of the dose–response curves between the three different groups of mice. The F_1 hybrid was no more sensitive than either one of the parental strains in this particular response.

Response to Gonadotrophin. (The following forms a part of the results of an experiment carried out by J. Leopold, as a summer student under my guidance.) Female mice about one month of age from inbred strains, *DBA/1*, *DBA/2*, *BALB/c*, *A* and the F_1 hybrid of the last-named two strains, were divided into dose groups. Chorionic gonadotrophin was serially diluted. One dose was assigned to each group and two injections were given to each mouse at 24-hr. intervals. Autopsy was made at about 12 hr. after the last injection. The presence of hæmorrhagic follicles in the ovaries was considered a positive response. The percentage of animals giving a positive response was calculated for each dose group. Probit transformation was made, and a linear regression was computed for each strain and hybrid according to the methods described by Finney[9]. The results are given in Table 2. The regression of the dose response appears to be largest for the *BALB/c* and least for the *A* strain; that of the F_1 hybrid fell between those of the parental mouse strains but close to that of the *A* strain. The difference in slope between the two *DBA* sublines, though not large, seems to show their genetic differences in the response as a consequence of separation in breeding for about twenty generations.

The published results using various hormones as sources of stimulation are given in Table 3. In addition to the differences in responses shown among inbred strains, out of nineteen comparisons of responses between F_1 hybrid mice and their parental inbred strains, ten hybrids fell between their parental strains, four were comparable to, and five greater than, either one of the parents.

Genetic Basis of Hormonal Response

A biological response, either physiological or morphological, varies within limits set by the genotype, although it is influenced greatly by environment. This is clearly indicated by: (1) the differences in response to various hormones between the inbred strains in the given examples; (2) response to selection for sensitivity to gonadotrophin[22]; (3) relative proportion of genetic to environmental variance in gonadotrophin assay[23]; (4) the heritability of iodine metabolism in the thyroids of mice[24], and the difference in response to thyroxine between inbred strains

Table 3. RELATIVE SENSITIVITY OR MAGNITUDE OF RESPONSE TO HORMONES IN INBRED AND F_1 HYBRID MICE

Hormone applied	Criterion of response	Relative sensitivity* or magnitude of response	Author
Œstrogen	Vaginal smear	$C_{57} > C_{57} \times CBA > CBA$ $C_{57} > CBA \times C_{57} > CBA$ $CBA \sim CBA \times A \sim A$	Trentin (ref. 10)
Œstrogen	Vaginal smear	$C_{57}BL > C3H \sim C$	Shimpkin (ref. 11)

PTU and thyroxine	Thyroid weight	$A/Jax > BAF_1 > C57BL/6$ $DBA/1 \sim DBA/2 \sim BDF_1 > C57BL/6$	Chai (ref. 21)
" "	Thyroid follicular cell height	$BAF_1 > C57BL/6 \sim A/Jax$ $BDF_1 > DBA/1 \ngtr DBA/2 \ngtr C57BL/6$	

Remarks: $BAF_1 = C57BL/6 \times A/Jax$; $CAF_1 = BALB/c \times A/Jax$; $BDF_1 = C57BL/6 \times DBA/2$

* The sequence is based mainly on observations of graphic illustrations and/or the mean values of responses. The differences between strains and F_1 hybrids in a response as given may not be statistically significant and the original authors might not fully agree with the given order.

of mice and their F_1 hybrids as determined by iodine turnover rate in the thyroids[25].

It may be pointed out particularly that on the results concerning the responses of *BALB/c* and *A* strains and their F_1 hybrids (Table 3), one is the response to œstrone and progesterone, measured by mammary gland area[13], and the other is response to œstrogen as measured by adrenal weight[14]. In both experiments, the F_1 hybrid fell between the parental strains and the order is the same as in assays using androgen[7] and gonadotrophin for stimulation. These results are from different laboratories, but in spite of possible differences in environmental conditions and in assay techniques, the same order of relative sensitivity has been obtained in mouse stocks. This may indicate that the same, or closely linked, genes control some of the related endocrine systems, and contributes further evidence toward the genetic determination of hormonal responses.

Except in a few cases (such as resistance to insulin in obese mice and responsiveness to pituitary extract in dwarf mice) where the action of a single gene can have a significant effect upon certain responses, the inheritance units determining hormonal responses in the mice commonly used in bioassays must be assumed at present to be polygenes. The biological properties of these polygenes may be considered to be the same as those which determine characters generally used in quantitative genetic studies. That is, their effects are small, additive and supplementary. The additive effects of polygenes in general have been found to be more important than dominance and epistatic effects, if the latter exist.

On this basis, the consequence in hormonal responses of F_1 hybrids in comparison to their parental strains may be tentatively postulated. When the parental strains differ greatly in a given biological response, it may be assumed that one strain possesses most of the alleles with plus effect and the other parent alleles with minus effects in the loci concerned. The consequence of combining one from each pair of alleles of these two sets as in the F_1 hybrids would result in an intermediate response or one close to it. It is supposed that in general the dominant effects are weaker than additive effects in polygenic inheritance. Therefore, even the net effects of dominance may not be exactly cancelled but the response in the F_1 will be unlikely to exceed those of either one or the other parental strain in the response concerned. This supposition seems to hold in many animal experiments dealing with quantitative characters and may hold in the present case. On the other hand, when the parental strains are similar in response, it is possible for the F_1 hybrids sometimes to give responses either greater or smaller than either parental strain, as a result of the supplementary effects or interaction of genes with the other genetic background. The responses to testosterone in four inbred strains of mice and two F_1 hybrids (Figs. 1 and 2), and results published by various investigators as given in Table 3, seem, in general, to support the above hypothesis. It is realized that this is a great over-simplification in this brief postulation of the genetic basis of hormonal responses, but, regrettably, until better understanding of the genetic and physiological properties of polygenes are arrived at, further speculation would be impractical.

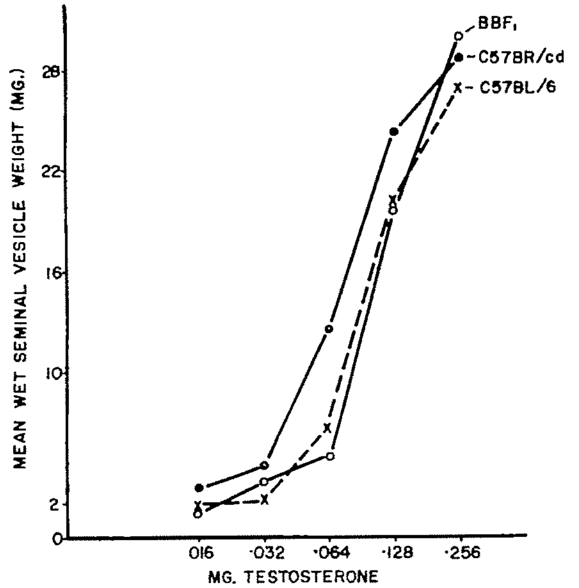

Fig. 1. Showing the response to graded doses of testosterone as measured by wet seminal vesicle weights in *C57BL/6*, *C57BR/cd* and their F_1 hybrid mice, *BBF*$_1$. It appears that there are no differences between them in sensitivity

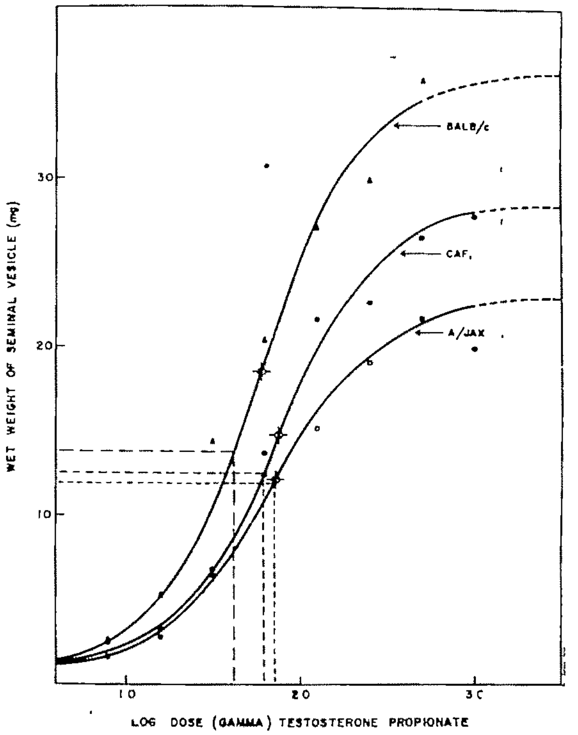

Fig. 2. Showing the distribution of seminal vesicle weights and fitted logistic curves for the *A/Jax*, *BALB/c* strains of mice and their F_1 hybrids treated with graded doses of testosterone propionate. The slope of the dose-response curve of *BALB/c* mice is greater than that of *A/Jax*, and that of their F_1 hybrid is about intermediate between those of the parental strains (from Chai, ref. 8, courtesy of *Anat. Rec.*)

Conclusions

The above data show that in the majority of cases the responses of the F_1 hybrids to various hormone stimulations fell between those of their parental strains. This indicates that the F_1 hybrids are not, in general, preferable to inbred mice in hormone assay in so far as the *b* value is concerned, for *b* is one of the two parameters in quantitative response and

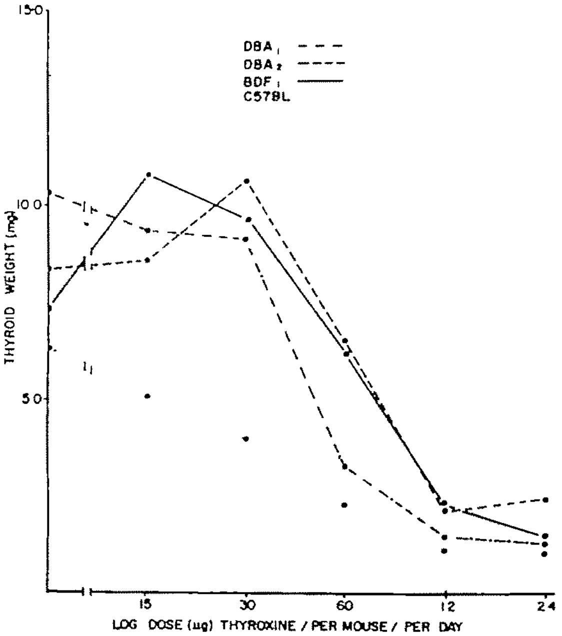

Fig. 3. Distribution of mean thyroid weights in the mice of *C57BL/6*, *DBA/1*, *DBA/2* and *BAF*$_1$ (*C57BL/6* × *DBA/2*). Each point represents a mean thyroid weight at a given dose from eight mice. Each mouse received a subcutaneous injection of thyroxine, one dose a day, for twenty days. All mice were on a diet of Purina Mouse Laboratory Chow mixed with 0 2 per cent of propylthiouracil during the treatment. Note the long linear portion of the curve for *C57BL* mice, which is desirable in bioassay, although the slope of the curve is smaller than that of the curves for the *DBA*'s and the *BAF*$_1$ (from Chai, ref. 21; courtesy of *J. Heredity*)

the only parameter in qualitative response in determining the precision of the assay.

The linear relationship between response and dose over the widest possible range of dose is another matter worthy of consideration. It is noticed that the response to both goitrogen and thyroxine in the *C57BL* mice was distributed linearly throughout practically all the dosages applied, whereas the linear portion for the F_1 hybrids fell within a limited range of dose[21] (Fig. 3). Whether this is due to better self-regulating properties of the F_1 hybrids, such that they can use the hormones more efficiently, is a problem remaining for further exploration.

It is generally claimed that F_1 hybrids are more uniform in growth and development than inbreds and this is, no doubt, a desirable feature in bioassay. The importance of body-size differences affecting the response depends on the degree of relationship between the criteria of response and body-size. In most cases, this can be handled satisfactorily by covariance analysis. The part of the variation in response as caused by differences in body-size should not be interpreted as the intrinsic difference in magnitude of reactivity of the assay animals themselves, but represents nothing more than the phenotypic heterogeneity of the assay subjects. More extensive data are needed to prove differences between the two types of genetically homogeneous populations, allowing for body-size differences. That is, whether there are basic differences in variation of reactivity to stimulation, which have not resulted from pre-existing anatomical or physiological differences in variability, remains to be studied.

It has been suggested that under unfavourable environmental conditions the homozygotes are more variable than the heterozygotes in growth and development. This might apply to biological responses and explain the differences obtained by investigators from different laboratories and the so-called transient effect in some laboratories. It is possible that the F_1 hybrids may stand long-distance shipment and change of environment better than inbreds, due to their better self-regulating ability and resistance to disease. This is a matter which needs to be considered in practice. On the same argument, it may be true that the homozygotes, such as the inbred mice, can be more subject to internal environmental changes of physiology and thus show more sensitive responses in bioassay than do heterozygotes. The recent report by Becker *et al.*[26] comparing growth response of inbred and non-inbred chickens at different nutritional levels seems to support this hypothesis.

In summary, F_1 hybrids do not necessarily have greater sensitivity as measured by the magnitude of responses at each dose-level. That F_1 hybrids are, in general, more uniform in growth and development and better adjusted to environmental changes than inbreds is often claimed. This is expected to affect the variability of response and may be an advantage of F_1 hybrids over inbreds in bioassays. Depending on the genetic background, some inbreds or F_1 hybrids may be more suitable for certain hormone assays than for others, and animals of some genotypes may be less variable in one environment than in another. For the assay of a given substance, the choice of assay animal—either an inbred or an F_1 hybrid—cannot be made in advance; it has to be based either on existing data or determined experimentally.

GEO- and RADIO-PHYSICS

A Day-time Maximum of Oblique Auroral Reflexions observed in the Auroral Zone

ALMOST all investigations of high-frequency and very high-frequency reflexions from aurora made in or near the auroral zone have given diurnal variation curves with one main maximum near local midnight[1-3]. An exception is the recent observations by Presnell *et al.*[4] at 216 Mc./s., made at College, which—for diffuse echoes only—has given two maxima, one in the morning and one in the afternoon with the peak between 1700 and 1900 L.T. Observers at lower latitudes have usually found two maxima in the night[5-8].

From four months records (March–June 1959) of aurorally propagated very high-frequency signals taken in the auroral zone at Kiruna Geophysical Observatory (geographic co-ordinates 67·8° N., 20·4° E., geomagnetic co-ordinates 65·3° N., 115·5° E.) and transmitted by the Finnish broadcasting station at Kemi (geographic co-ordinates 65·8° N., 24·8° E., geomagnetic co-ordinates 62·5° N., 117·6° E.) a diurnal variation curve with two maxima has been found (cf. Fig. 1). One of these maxima is in day-time between 1200 and 1600 M.E.T. The experimental points include all observed reflexions. This is in remarkable contrast to the diurnal variation mentioned above, which was observed by radar methods at Kiruna (in 1951–52) and at other places in auroral zone latitudes.

The transmissions studied at Kiruna have a frequency of 92·8 Mc./s. The broadcasting station, 310 km. distant, has sent out continuous waves in the periods between programme transmissions. The radiated power is 8·9 kW. and the polarization horizontal. A 'Servo' model *R* 5200-*A*2 receiver and a five-element Yagi antenna are used. The sensitivity is better than 1 μV. for 50 mW. output for a band-width of 25 kc./s.

There is no doubt that this auroral echo day-time maximum is real. The day-time echoes have the same signal characteristics observable[2] as night echoes[1] on the Esterline Angus records. The direction distributions for day- and night-maxima are approximately the same ; this has been determined by means of rotary antennæ. The day-time maximum has been found also in monitoring another transmitter (Östersund in central Sweden, 87·9 Mc./s.).

The local time for the afternoon echo maximum of Fig. 1 is much earlier than that found by any other observers, so far as we are aware. If the geomagnetic time for the maximum is investigated, the difference from the time of maximum found on the western hemisphere (especially in Alaska) is reduced by several hours, but also the geomagnetic time for the afternoon maximum found at Kiruna is earlier than reported by anybody else. Recent work at a frequency of 216 Mc./s. (ref. 4) has given an afternoon maximum, but only for a special type of echo, the so-called diffuse echoes. The difference between the geomagnetic time for the afternoon maximum reported by Presnell *et al.*[4] and that shown in Fig. 1 is about 1 hr.

The investigation at Kiruna will be extended over a longer period of time, and it is hoped that the recorded material will show if the diurnal variation curve described above is characteristic of observations of oblique auroral very high-frequency reflexions at Kiruna for longer periods, or only for the four months analysed.

Observations of Ionization induced by Artificial Earth Satellites

While monitoring a remote continuous-wave station at the Ohio State University Radio Observatory, it has been found that large enhancements of signals often occur at the times of near approach of an artificial Earth satellite. The enhancements are of such magnitude as to indicate extensive ionization with scattering cross-section several orders of magnitude greater than the physical cross-section of the satellite[1-3]. In these observations it has been convenient to monitor the National Bureau of Standards time service station *WWV* near Washington, D.C., at a distance of 330 miles from Columbus. This communication describes some additional observations of the phenomenon.

Between January 9 and February 7, 1959, the enhancements of signals of *WWV* on 20 Mc./s. were recorded on three or four passes of *Sputnik III* each night (between local midnight and 6 a.m.), while recordings of the satellite transmissions on 20·0045 Mc./s. were recorded to determine the time of near approach. The passes during this period were typically west to east with near approach over Hudson Bay (north of Columbus). A three-element beam antenna directed to the north was used for reception. The *WWV* records were divided into approximately 100-min. intervals centred on the near approach time of *Sputnik III*. All *WWV* enhancements of more than a constant minimum magnitude and more than 30 sec. in duration were taken as significant. Adding all such enhancements (about 200) for a total of 50 passes on 14 nights (3–4 passes per night) a histogram was obtained. Averages for each 5-min. period were taken and a smoothed curve drawn through these values. The result is shown in Fig. 1.

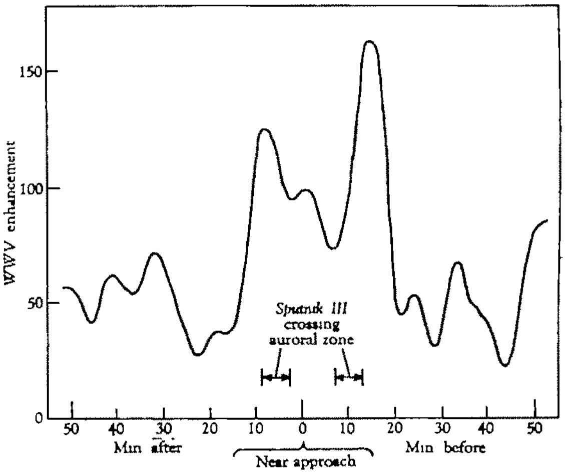

Fig 1. Enhancements of *WWV* 20-Mc./s. signals as a function of time before and after the near approach of *Sputnik III* for 50 passes on 14 nights during January and February 1959

This graph gives the amount of *WWV* enhancement (number of enhancements times magnitude) to an arbitrary scale as a function of time before and after the near approach of *Sputnik III*. A peak occurs at the time of near approach, but larger peaks somewhat before and after. These three peaks, grouped around the near approach, are as much as 10 times greater than the standard deviation in the remainder of the graph, which makes it very unlikely that they are due to a random process. It is to be noted that the largest peaks are 15 min. before (precursor enhancement) and 8 min. after near approach (post-enhancement). It may be significant that these times correspond approximately to the times the satellite was, on the average, passing through the auroral zone (see Fig. 1). A possible hypothesis for explaining this effect is that the satellite encountered regions of high-particle density in the auroral zone, scattering material into ionized clouds or streams which travelled closer to Columbus with reflexions from these clouds causing many of the observed signal enhancements.

In order to obtain more data on the ionized clouds, a radar transmitter of about 600-W. peak power was installed at the prime focus of the Ohio State University 360-ft. radio telescope[4]. At the time, the parabola was completed but the flat reflector had not been assembled, so that the parabola was unobstructed to the north. Using frequencies between 17 and 19 Mc./s., a fan beam about 10° wide by 50° high was produced above the northern horizon, with a gain of nearly 20 decibels. The receiver was located about 20 miles south at Columbus. The receiver output was displayed on a *z*-type oscilloscope and was recorded on 35-mm. film moving 2 cm./min. With this arrangement a number of significant records were obtained. Fig. 2 shows one of these, obtained on February 20, 1959. Time increases to the left and range increases vertically downward. Between 11.13 and 11.15 p.m., *Sputnik III* was in the beam of the 360-ft. parabola travelling north-west to south-east at an average range of about 1,400 miles (height 860 miles). At 11.13 several traces appear on the film which radiate from the point *A*. At 11.13·8 two traces appear on the film which radiate from the point *B* and at 11.14·8 there are two traces radiating from point *C*. Points *A*, *B* and *C* are all close to the range of the satellite (dashed line) as calculated from ephemeris and other data with the satellite reaching its point of near approach north-east of Columbus about 11.17 p.m. at a range of about 1,200 miles. At point *C* there are two faint traces close to the range of the satellite. These may be due to reflexions from ionization at or close to the satellite.

It is postulated that at points *A*, *B* and *C* the satellite encountered regions of high density scattering a number of particle clouds. Clouds from the radiant points *B* and *C* approached within about 400 miles of Columbus. (Similar particle clouds may also account for the precursor enhancement peak in

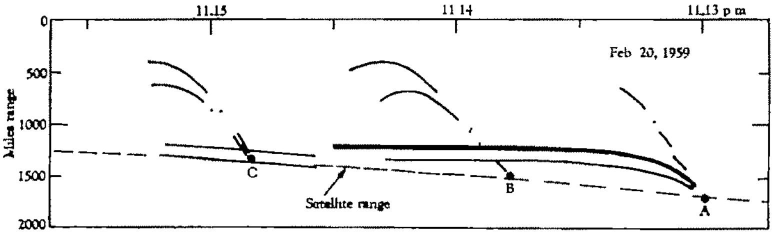

Fig. 2. Radar traces of moving ionized clouds which appear to originate at the range of an artificial Earth satellite (*Sputnik III*) as it passed through the beam of the 360-ft. parabola of the Ohio State University radio telescope

Fig. 1.) The two traces lasting about 90 sec. extending from the radiant point *A* start out with hyperbolic shape but flatten out to a constant range, suggesting that the particular clouds of particles producing them left an ionized wake nearly perpendicular to the radius vector from Columbus. From the slopes of the traces in Fig. 2, the velocities of the particle clouds radiating from *A*, *B* and *C* are between 30 and 150 km./s. These values are much in excess of the actual velocity of the satellite of about 7 km./s. Such velocities might be explained by collisions of the satellite with fast corpuscular streams. Assuming elastic collisions and an exactly head-on geometry of encounter, the resulting particle-velocity is equal to the velocity of the incident stream plus twice that of the satellite.

It should be mentioned in connexion with Fig. 2 that at about 11.13 p.m. the signals from the *Sputnik III* transmitter on 20·0045 Mc./s., which had been very strong, dropped to a very low level for about 1 min., after which their strength returned. The decrease in signal coincided with the beginning of the radar traces from the radiant point *A*, suggesting the possibility that the ionized particles encountered or produced at this time resulted in absorption or scattering of the signal from the transmitter on the satellite, while at the same time the particles acted as a reflecting or back-scattering medium for the radar signals.

The work described has been supported in part by the U.S. Army Rocket and Guided Missile Agency through a contract with the Ohio State University Research Foundation, and in part by the Fund for Basic Research of the University.

Temperatures within the Earth's Core

IN a recent communication, Strong[1] gave the results of an experimental determination of the fusion curve of iron up to a pressure of 96,000 atmospheres. On the usual assumption that the Earth's core is composed of iron, he extrapolated his results to obtain a value of 2,610 ± 200° K. for the melting point in the core at the core–mantle boundary. His experimental results fitted Simon's[2] equation:

$$\frac{p}{a} = \left(\frac{T_m}{T_0}\right)^c - 1 \tag{1}$$

with the constants $a = 75{,}000$ atmospheres and $c = 8$. In this equation p is the pressure in atmospheres, T_0 the melting temperature in degrees Kelvin at one atmosphere (that is, $T_0 = 1{,}805°$ K.), and T_m the melting temperature at the pressure p. Estimates of the melting point in the Earth's core obtained by Strong are appreciably lower than those obtained using Simon's values for the constants a and c, and only about one-half of those obtained using Gilvarry's[3] more recent values. Moreover, the gradient of the melting point curve is much lower than in these previous estimates. The value of 2,610° K. for the melting point at the core–mantle boundary is particularly interesting in view of Verhoogen's[4] conclusion that the temperature there is not likely to exceed 2,700° K. and his previous estimate[5] of 2,500° C. as the maximum, which was based on the hypothesis that the maximum observed surface temperature of lavas reflects the maximum temperature in the mantle. Since seismic evidence indicates that the outer core in any event is liquid, these two results of Strong and Verhoogen taken together fix the temperature T_1 at the core–mantle boundary rather precisely, namely:

$$2{,}610 < T_1 < 2{,}700 \tag{2}$$

so that a value of 2,650° K. for T_1 seems reasonable.

The only estimate of the melting-point temperature in the mantle is that due to Uffen[6], who obtained a value of 5,000° K. at the core–mantle boundary. With the low melting-point temperatures in the core as indicated by Strong it is worth reconsidering the early history of the Earth's interior. In my[7] explanation of the solid inner core for an Earth cooling from a molten state, it is necessary to postulate a discontinuous decrease in the melting point at the core–mantle boundary, and a higher melting point at the centre of the Earth than at the bottom of the mantle. This last requirement is certainly not met now unless Uffen's figures can be considerably reduced. A completely molten Earth would thus solidify from the core boundary and progress outwards, leaving the entire core liquid. A solid inner core could arise, however, on the hypothesis of a cold origin for the Earth, in which case melting would progress inwards from the core–mantle boundary as the temperature of the interior increased. As shown below this seems very probable.

The flatness of the gradient of the melting point curve makes it instructive to re-estimate the adiabatic gradient in the core. Vallé's estimate[8], based on seismic data and solid state theory, was greater than Simon's value of the melting point gradient and is much greater than the new values of Strong. If this is true, it would be impossible for an Earth cooling from a molten state to leave a solid inner core and a liquid outer core. Far more important, convection currents in the core which are required by most modern theories of the Earth's magnetic field, could not occur. I have thus re-computed the adiabatic gradient in the outer core, on the basis of my temperature–pressure hypothesis[9]. On this theory, the adiabatic gradient depends on the temperature and is given by:

$$\frac{\mathrm{d}T}{\mathrm{d}p} = \frac{T}{\rho\, c_p\, (C + bp)} \tag{3}$$

where ρ is the density, c_p the specific heat at constant pressure and C and b constants ($C = 2{\cdot}4 \times 10^{4}$° K., $b = 6{\cdot}2 \times 10^{-8}$° K. cm.^{2}/dyne). Equation 3 can be integrated to give:

$$\log_e T = \int \frac{\mathrm{d}p}{\rho\, c_p\, (C + bp)} \tag{4}$$

Assuming c_p to be constant[8] ($1{\cdot}24 \times 10^7$ ergs/gm. ° K.), and the temperature T_1 at the core–mantle boundary to be 2,650° K. (cf. the inequality (2)), the adiabatic temperature can be estimated at any depth within the core, and, by differentiation, the adiabatic temperature gradient. It is found that the melting-point gradient exceeds the adiabatic temperature gradient so that convection in the core would be possible. The adiabatic temperature at the boundary of the inner core estimated from equation (4) is 2,900° K. The melting point at this depth, calculated from equation (1), has exactly the same value. Although the agreement between these two estimates may well be fortuitous, it would appear that the inner core is solid.

PHYSICS

Graphitization of Diamond

IN an earlier article in *Nature*[1] I reported some results of a study of the high-temperature transformation of diamond to graphite. In this work diamond powder of 0–1μ particle size was used. Samples which had been heated in vacuum to various temperatures in the range 1,000–2,000° C. were obtained and these were investigated by microscopy and diffraction in a Siemens electron microscope (Elmiskop I). Specimens which had not been heated above about 1,200° C. gave diamond diffraction patterns only, those which had been heated to 2,000° C. gave graphite patterns only, and those which had been heated to about 1,600° C. gave both diamond and graphite patterns and also some extra spots not due to either diamond or graphite. It was suggested that these extra spots were due to some intermediate arrangement of carbon atoms, possibly a regular array of diamond-like and graphite-like regions produced during the graphitization. More recent work has shown that this interpretation of the results is not justified, and it is the purpose of the present communication to describe the diffraction patterns in more detail and to give such interpretation of them as at present seems reasonable.

The transmission electron diffraction patterns were complicated, and it was not possible to obtain great accuracy in the calculated Bragg spacings because of refraction effects and other distortions of the patterns. Except for two specimens the highest spacing found was between 3·0 and 3·1 Å. The two exceptions showed reflexions at spacings of 6·0 Å. for the one and 4·1 and 3·6 Å. for the other. Lower spacings were 2·8, 2·6, 2·5, 2·4, 2·2 Å., etc., but more accurate values were afterwards obtained from X-ray powder photographs (obtained by Dr. P. Gay, Department of Mineralogy, Cambridge). These gave the values 2·60, 2·55, 2·50, 2·36, 2·18, 1·99, 1·89, 1·535, 1·419, 1·310, 1·134, 1·086 Å.

It was also found (originally by A. I. Bailey and J. W. Menter in 1950, private communication) that, if large single-crystal diamonds which had been heated to red heat in a flame were examined by reflexion electron diffraction, both regular cross-grating spot patterns and continuous ring patterns could be obtained. The spot patterns gave spacings of 8·7, 6·2, 5·8, 4·4, 3·6, and 2·5 Å. The high-spacing part of the ring patterns was lost in the shadow of the specimen edge; but rings 3·1, 2·8, 2·63, 2·52, 2·35, 2·18 Å. and lower were seen. The spacings were the same as in the transmission patterns of graphitized diamond dust. These reflexions, with the exception of those at 5·8 and 2·55 Å., can all be interpreted in terms of a cubic structure of cell side 12·3 Å. Almost all the results can thus be accounted for, and it was thought at the time that the earlier communication[1] was written that an intermediate phase must have been formed since no likely impurity having a unit cell of these dimensions exists. Furthermore, the appearance of dark-field electron micrographs suggested that the material having this structure was distributed uniformly and homogeneously through the diamond sample[2].

However, the diamond samples which gave these diffraction patterns were found by spectrographic analysis (done by Messrs. Johnson Matthey, Ltd.) to contain about 1 per cent of silicon. When the experiments were afterwards repeated using a purer diamond sample (0·0002 per cent silicon), no extra reflexions were found in the transmission electron diffraction patterns, and only one very weak extra reflexion—at 1·89 Å.—in the X-ray powder photographs. It therefore seems that a silicon compound was responsible for nearly all the extra reflexions and it is almost certain that this was silicon carbide. With the exception of the line at 1·89 Å., all the extra lines in the X-ray powder photographs agreed in spacings and relative intensities with those in a comparison pattern from silicon carbide. The spacings from most of the extra spots in the transmission electron diffraction patterns agreed with the values for silicon carbide, but there were a few exceptions—weak reflexions at 6·0, 4·1, 3·6, 3·0, and 2·8 Å. These reflexions were presumably due to some other impurity; but this has not yet been identified.

The flame-heated diamonds also gave extra reflexions when examined by reflexion electron diffraction. The ring patterns gave the same spacings as were found for the graphitized diamond dust and presumably were caused by the presence of the same impurities. The cross-grating spot patterns gave larger spacings than were found from the other patterns. They may well be due to an impurity; but again this has not yet been identified. The fact that nearly all the lattice spacings fit a cubic lattice of cell side 12·3 Å. seems to be fortuitous, especially as most of the larger spacings were only observed with the one type of specimen.

It is concluded that the hypothesis of an intermediate structure of carbon atoms is not justified, and that the extra spots and rings in the diffraction patterns were probably caused by the presence of silicon carbide and other unidentified impurities. Silicon carbide has also been found to be a contaminant of heated diamond by Raal, whose results are published in the following communication. The two sets of results are in good agreement and show the formation of silicon carbide at similar temperatures; but the source of the silicon was different—in Raal's case it was the fire-clay boat used to contain the diamond, in mine an impurity in the diamond sample

I wish to thank Dr. F. P. Bowden for his interest in this work, and Messrs. Industrial Distributors (1946), Ltd., for a grant to the Laboratory.

Alleged Formation of an Intermediate Diamond Structure on Heating Diamond

IT was shown by Seal[1] that little change was produced by heating natural diamond powders to 1,200° C. in a vacuum (10^{-4} mm. mercury) for periods of 15–30 min. Heating the powders to 2,000° C. resulted in a complete transformation to graphite. For temperatures of about 1,500° C. both diamond and graphite could afterwards be detected, and, in addition, the electron diffraction patterns showed extra spots not due to either diamond or graphite. Seal advanced the theory that these extra reflexions were due to some intermediate arrangement of carbon atoms in diamond, possibly a regular array of diamond and graphite-like regions.

X-ray diffraction patterns of the samples gave extra lines, by far the strongest of which corresponded with a lattice spacing of 2·51 Å. Also, it was stated that spectrographic analyses of the diamond powders before and after heating showed a chief impurity of 1 per cent silicon (Seal, M., private communication).

In a current programme of investigation diamond powders have been heated to about 1,400° C. in an inert atmosphere for various lengths of time. X-ray as well as spectrographic analyses of the powders before and after heating have confirmed the observation of Seal; but, in the light of our experiments, the existence of an intermediate atom structure in diamond after heat treatment can be discounted, and an obvious explanation for the extra X-ray reflexions and the increased silicon content of the heated diamond powder is given.

On measuring the extra lines of the X-ray pattern of the heated diamond powders the strongest reflexion was found indeed to correspond with a lattice spacing of 2·51 Å. In addition, two reasonably strong reflexions for spacings of 1·54 Å. and 1·31 Å. were found. Reference to the ASTM X-ray data card system identified these extra reflexions as being due, almost certainly, to silicon carbide.

This result is significant in the light of the fact that a chief impurity of 1 per cent of silicon is quoted by Seal for the heated diamond powders, whereas a silicon content of more than 0·1 per cent is seldom found for natural unheated diamond[3].

According to Tammann[3] the reaction between silicon and carbon to form silicon carbide starts at 1,340° C.

It appears, therefore, that the extra X-ray reflexions as well as the high silicon impurity content of the heated diamond powder are attributable to the formation of some silicon carbide as a result of chemical reaction between the diamond powder and silicon at an elevated temperature. In Seal's experiments the heating was done in crucibles of pure graphite; but the silicon might have been present initially as a contaminant or might have originated from his furnace. In our experiments, boats of fire-clay, which is essentially an aluminium silicate, were used for the heating, and it is very likely that at 1,400° C. or higher they react either with the pure diamond or a graphitized layer on the surface of the diamond to give silicon carbide.

In order to verify this a diamond powder was heated at 1,400° C. in a platinum spoon for several hours and analysed by means of X-rays as well as spectrographically. Extra X-ray reflexions were completely absent, and as can be seen from Table 1, the silicon content is not more than normally found in diamond powder.

Table 1

Diamond powder	Silicon content (percentage by weight)	Extra X-ray reflexions
Unheated	0·01	No
Heated to 1,400° C. in fire-clay boat	1·00	Yes
Heated to 1,400° C. in platinum spoon	0·04	No
Heated to 1,400° C. in fire-clay boat and treated in hydrofluoric acid	1·00	Yes
Heated to 1,400° C. in fire-clay boat and subjected to sodium-hydroxide–sodium nitrite fusion	0·01	No

A further test was done to substantiate whether, in fact, silicon carbide is formed and whether the increased silicon content of the powder heated in the fire-clay boat is not just a result of contamination from the latter.

The heated powder was treated for several hours in hot hydrofluoric acid which digests silicon in any form except as the carbide. The extra X-ray reflexions and high silicon content of the powder remained unaltered as is evident from Table 1. On subjecting this powder to a sodium hydroxide–sodium nitrite fusion which is capable of removing silicon carbide, the silicon content, as depicted in Table 1, becomes normal again and the extra X-ray reflexions are absent.

From the above considerations it is evident that the extra X-ray and electron diffraction spots observed by Seal in heat-treated diamond powders are due to the existence of easily detectable amounts of silicon carbide as a result of chemical reaction at elevated temperatures.

I wish to thank Drs. H. J. Nel and A. R. Roy for their interest and helpful discussions and Messrs. Industrial Distributors (1946), Ltd., for permission to publish this communication.

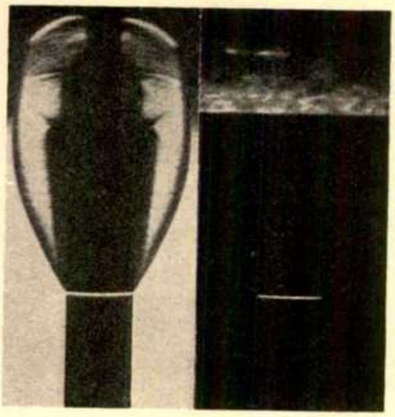
Emission and Absorption of Light behind the Detonation Front

WHEN a high explosive detonates, the measurement of the true emission of light from the detonation gases is of great interest. In air, however, the expanding detonation gas is enveloped in a compressed layer of the displaced air, which acquires a high temperature (*c.* 8,000° K. at atmospheric pressure) and emits an intense light. An easy way of eliminating the luminous layer of air is to immerse the charge in water. Charges of *TNT* and phlegmatized *PETN*, for example, then show a narrow luminous zone



(a) (b)

Fig. 1

behind the detonation front. Fig. 1 shows instantaneous pictures (exposure time, 0·03 µsec.) of detonating cylinders of phlegmatized *PETN* of 1·55 gm./cm.^{3} density and 25-mm. diameter, first with (1*a*) then without (1*b*) background light of a detonated *TNT*-ball. (In Fig. 1*b* and Fig. 2 the upper end of the charge was above the surface.)

Fig. 1*a* shows that the expanding detonation gas is non-transparent to the background light. This implies that absorption of light is important in determining the light observed. In the case of phlegmatized *PETN* (10 per cent wax), which is very deficient in oxygen, this may be due to particles of carbon forming a light-absorbing screen on the cooled surface layer of the detonation gas. C. H. Johansson and L. Sternhoff[1] have recently shown that in *TNT*, even the narrow band of light disappears if the charge is exposed to the pressure wave from a neighbouring charge which has detonated somewhat sooner. In view of these results, the visible luminous zone cannot be assumed to correspond to the reaction zone.

In order to eliminate the absorption of light by carbon particles, similar tests were made with blasting gelatine freed from air bubbles. Instantaneous photographs show that light is emitted from a greater area with gradually decreasing intensity backwards. The diameter of the charge is, however, possibly too small for black-body emission.

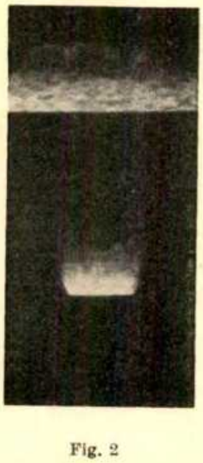


Fig. 2

To get the intense light emission of *PETN* without absorption at the surface, we have made tests with charges with a varnished core of phlegmatized *PETN* and a surface layer of blasting gelatine intended to prevent the cooling off at the surface of the detonation gases of *PETN*. The coating of varnish prevented the dissolution of the *PETN* by the blasting gelatine. Fig. 2 shows an instantaneous photograph of a detonating charge of a 25-mm. *PETN* cylinder coated with a 1-mm. layer of blasting gelatine freed from air bubbles. In this case the light is emitted over a wide area behind the front and corresponds probably much better to the temperature distribution in the expanding detonation gas of *PETN* than the narrow luminous zone in Fig. 1.

This investigation has been carried out with support of the Swedish Detonation Research Foundation.

Effect of Corona on Travelling Waves

A NEW phenomenon of impulse corona has been observed with voltage waves of relatively long wave-fronts on a 33-kV. overhead line. The wave-shape at the sending end is 5·7/19·3 µsec. nominal. The accompanying oscillograms show typical waves recorded at a point 2·08 miles away. As the voltage exceeds the corona threshold, the wave-front shows the well-known phenomenon that part of it is sheared off due to corona losses. However, the voltage clearly recovers before its peak value is reached whereas previous observations made with wave-fronts of 1·5 µsec. or less show that this shearing effect extends to the wave tail. After the tests on which this communication is based had been completed, it was found that this recovery of voltage had also been observed by Mita and others[1] on a model line with waves of 2·2 and 4·2 µsec. fronts. As can be seen from the oscillograms, the rate of recovery is much faster for a negative wave than for a positive wave.

This phenomenon suggests that the initial intense ionization is halted, completely or almost completely, by the space charge of its own creation. This view is supported by the cessation of the high-frequency oscillation on the positive wave just before the voltage recovers. This high-frequency oscillation had also been observed to be associated with positive corona during earlier tests on 33-kV. and 132-kV. lines[2]. The fact that this recovery of voltage was not previously observed is probably due to the short front-durations of the impulse waves employed so that only the effect of the initial stage of the corona process became apparent.

Clearly, the distortion of the wave front due to corona cannot be considered to be independent of the front-duration as has been assumed in existing theory[2,3]. Either the theory has to be modified or a new approach adopted.

Several authors have measured the relation between impulse voltage $e(t)$ and corona charge $q(t)$. The results obtained by Aso[4] on a thin wire (0·6 mm. diam.) inside a concentric cylinder (10 cm. inside dia.) show that when the voltage exceeds the corona threshold dq/de increases rapidly to a fairly constant value and then decreases to a small value. It can be

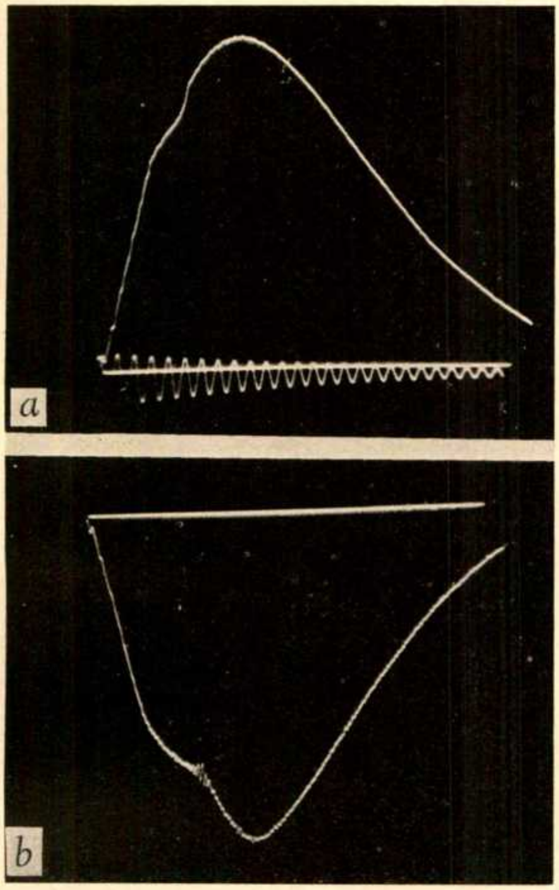

Fig. 1. *a*, Negative wave (timing oscillation, 1 Mc./s.); *b*, positive wave

shown mathematically that if the $q \sim e$ curve for the test line shows this variation in dq/de then the voltage will recover as observed.

A full report will appear elsewhere. Acknowledgment is due to the Director of the Electrical Research Association for permission to publish this communication.

RADIATION CHEMISTRY

Effect of Ionizing Radiation upon Xanthosine in Dilute Aqueous Solution

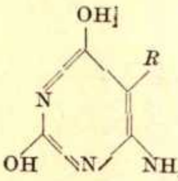
IT was reported earlier[1] that irradiation of an aqueous solution of guanosine with 15 MeV. electrons opened the imidazole ring to form 2 : 4-diamino-5-formamido-6-hydroxypyrimidine riboside. This communication reports that a similar ring-opening occurs when an aqueous solution of xanthosine is irradiated.

Table 1. R_F VALUES OF ULTRA-VIOLET ABSORBING COMPOUNDS OBTAINED FROM AN IRRADIATED AQUEOUS SOLUTION OF XANTHOSINE

Band	Solvent 1 (ref. 2)	Solvent 2 (ref. 3)	Solvent 3 (ref. 4)	Identity
1	0·46	0·31	0·67	xanthine
2	0·64	0·20	0·90	xanthosine
3	0·73	0·18	0·81	I
4	0·85	0·09	0·94	I-riboside

An aqueous solution of xanthosine, concentration 10^{-3} *M*, and containing 10^{-3} *M* neutral phosphate buffer, was irradiated with 15 MeV. electrons to a dose of 8×10^5 rads. The irradiated solution and the control solution were analysed by paper chromatography, using an 85 per cent saturated aqueous solution of ammonium bicarbonate as a solvent[2] (solvent 1). While the control solution gave a single ultra-violet absorbing band, the irradiated solution was resolved into four bands (Table 1) which were identified by their R_F's in solvents 1, 2[3] and 3[4], and the ultra-violet spectra of their eluates.

Band 1 was identified as xanthine, and is assumed to be liberated by hydrolysis following radical attack upon the ribose moiety[5]. Band 2 is unchanged solute. The spectra of bands 3 and 4 were similar with a single absorption maximum, the maximum of band 4 being at a longer wave-length (270 mμ) than that of band 3 (262 mμ). Analogy with results obtained for guanosine[1] suggested that band 3 is 2 : 6-dihydroxy-4-amino-5-formamido-pyrimidine (I) and band 4 its riboside.



I. (R = NHCHO)

II. ($R = NH_2$)

The identity of band 3 was confirmed by comparing its R_F's and ultra-violet spectra with those of an authentic specimen of I, kindly supplied by Mr. G. M. Timmis. Their R_F's in solvents 1, 2 and 3 (Table 1), and their ultra-violet spectra at *p*H 7 and 12 were identical (Fig. 1). At *p*H 1 and room temperature the ultra-violet absorption decreased slowly. In view of the well-known acid lability of formyl groups, it seemed possible that I was slowly deformylated in acid to 2,6-dihydroxy-4,5-diaminopyrimidine (II). This was essentially confirmed when, after leaving I in 0·1 *N* hydrochloric acid for 48 hr., the resulting spectra were found to be identical with those published for II[6]. Accordingly, an acid spectrum of I was obtained by dissolving it in 98 per cent formic acid (see Fig. 1), which gave no spectral change over a period of 20 hr.

Band 4 was identified as the riboside of I by identifying the sugar and ultra-violet absorbing compounds released during acid hydrolysis. Band 4 was separated from free ribose by running it in solvent 2, eluted and hydrolysed in 85 per cent formic acid at 100° C. for 5 min. When the hydrolysate was run in solvent 2 an ultra-violet absorbing product was detected with R_F's and ultra-violet spectra identical with those for I. A sugar spot, with an R_F identical with that for ribose, was detected by spraying the paper with aniline-hydrogen-phthalate[8]. Xanthosine is readily hydrolysed in acid[9]. Under the conditions

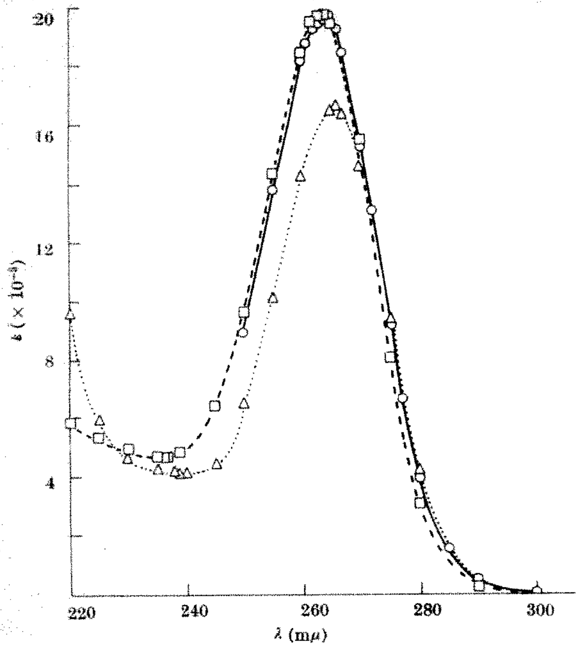


Fig. 1. Ultra-violet absorption spectra of 2 : 6-dihydroxy-4-amino-5-formamido-pyrimidine (I). ○—○, in 98 per cent formic acid ; □- - - -□, at pH 7 ; △· · · ·△ at pH 12

described above xanthosine and I-riboside (band 4) were completely hydrolysed, while under milder conditions, namely, 85 per cent formic acid at room temperature, half the starting material was hydrolysed in 22 hr. and no difference in the rates of hydrolysis of xanthosine and I-riboside was observed.

It is now established that the imidazole ring is opened when aqueous solutions of guanosine and xanthosine are irradiated. Results obtained with adenosine and inosine, to be published shortly, show that here too the imidazole ring is opened ; this seems to be a general reaction for purine nucleosides. When an electrophilic reagent approaches the purine ring C–8 appears to have the highest electron density[10]. Assuming that the chemical action of ionizing radiation is by OH radicals[11], attack at C–8 would be consistent with the electron configuration of the purine ring, mentioned above. Xanthosine is changed at a rate ($=G$) of 1·2 molecules per 100 eV. absorbed energy, which is low compared with the rate of formation of OH radicals ($G=2{\cdot}8$)[12]. Presumably the reaction is complicated by unknown factors, for example, a back-reaction, upon which the present results shed no light.

I wish to thank Prof. J. Rotblat, St. Bartholomew's Hospital Medical School, for his kind permission to use the linear accelerator. The Medical Research Council is thanked for its financial support when this work was begun at the Barnato-Joel Laboratories, Middlesex Hospital, London. Identification of products was completed at the Chester Beatty Research Institute, Institute of Cancer Research, with the financial support of the William Shepherd Fund, and by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign, the Jane Coffin Childs Memorial Fund for Medical Research, the Anna Fuller Fund, and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

CHEMISTRY

Simple Non-gassing Electrodes for Use in Electrophoresis

THE electrodes conventionally used in electrophoresis are noble metal (usually platinum), metal/metal ion (for example, Cu/Cu^{2+}) and metal/insoluble metal salt (for example, $\text{Ag}/\text{AgCl}/\text{Cl}^-$). With the last two types the apparatus must be provided with convection barriers to prevent metal ions in the electrode compartments from contaminating the experimental material. Platinum electrodes, even if platinized, permit only a limited current density (less than 2 m.amp./cm.^{2}) without giving an evolution of gas bubbles which disturbs the observations in closed electrophoresis systems such as are used in the moving boundary and microscopic methods. We wish to describe here the general conditions under which palladium–hydrogen electrodes can be used to provide adequate current densities for electrophoresis without gassing or danger of contamination from heavy metals.

Almost a century ago Graham found that palladium metal would dissolve considerable amounts of hydrogen when used as the cathode in an electrolytic cell[1]. Present evidence indicates that the following electrolytic reactions take place at palladium electrodes[2] :

$$x\text{H}_3\text{O}^+ + \text{Pd} + xe^- = \text{PdH}_x + x\text{H}_2\text{O} \quad (\text{at low } p\text{H})$$
$$x\text{H}_2\text{O} + \text{Pd} + xe^- = \text{PdH}_x + x\text{OH}^- \quad (\text{at high } p\text{H})$$

The PdH_x formed at the cathode is not a definite chemical compound such as a hydride, but more nearly an alloy of palladium with hydrogen[3].

So long as the cathodic formation of PdH_x is fast compared with the combination reactions of atomic hydrogen on the surface of the electrode, no molecular hydrogen will be evolved until the solubility of hydrogen in palladium is exceeded at a hydrogen/palladium atomic ratio of about 0·9 (ref. 4). At the anode, oxygen or other gases will not be evolved so long as the electrode has a store of atomic hydrogen and the current density is not excessive. Obviously the anode must be cathodically charged with hydrogen before use.

While similar reactions may occur at platinized platinum electrodes, the situation is considerably altered by the fact that the total amount of hydrogen stored is limited to surface adsorption. The advantage of palladium as a current-carrying electrode lies in its capacity to absorb considerable amounts of hydrogen.

Three possible ways of using palladium electrodes are indicated schematically in Fig. 1,*a*, *b*, *c*. In the simplest system, Fig. 1,*a*, the electrodes are immersed in the solution, filling the electrode chamber. Here the anode must be precharged with an amount of hydrogen sufficient for the electrophoretic run. Relatively small electrodes can store ample amounts of hydrogen for many purposes ; for example, a palladium anode weighing 1 gm. will, if precharged to a hydrogen/palladium atomic ratio of 0·5, deliver a current of 10 m.amp. for more than 12 hr. before the hydrogen is exhausted.
